When chromophore A can adopt a chiral conformation and B can change its conformation upon binding, some additional sources of ICD induced by chromophore B should be considered. The ICD is generally assumed to be the difference

$$\text{ICD} = \Delta\text{CD} = \text{CD}(\text{B} + \text{A}) - \text{CD}(\text{B}) - \text{CD}(\text{A}) = 0 \quad [6]$$

Figure 4 Measured ICD of APF (see Formula) bound to [poly(dAdT)]₂ [spectra (a)–(f)] and to [poly(dGdC)]₂ [spectrum (g)]. The strongly positive ICD in spectrum (a) (drug:DNA phosphate ratio $r=0.001$) is consistent with minor groove binding (see **Figure 3**), while increasing binding ratios ($r=0.02, 0.04, 0.08, 0.16$ and 0.31) give a gradually increasing contribution of CD due to exciton coupling between adjacently bound APF molecules. The weak positive ICD in [Poly(dGdC)]₂ is consistent with intercalation (transition moment along the DNA dyad axis, see **Figure 2**). Reproduced with permission of the American Chemical Society from Jansen, Lincoln, and Nördén (1993) *Biochemistry* 32: 6605.

where A = achiral molecule (drug), in which case CD(A) = 0, and B = chiral molecule (DNA). However, the net Δ CD may also have a contribution due to a change of conformation in B:

$$\Delta\text{CD} = \text{ICD}(\text{A}) + \delta\text{CD}(\text{conf B}) \quad [7]$$

where $\delta\text{CD}(\text{conf B})$ = CD change of B due to conformational change of B upon interaction with A.

Since ICD(A) is the true ICD, providing information about the interaction, it is recommended that one corrects, if possible, for any contributions due to conformational change of B [$\Delta\text{CD} - \delta\text{CD}(\text{conf B})$]. Three contributions to the ICD of A may be distinguished:

$$\text{ICD}(\text{A}) = \text{ICD}(\text{A})_{\text{el}} + \delta\text{CD}(\text{conf A}) + \delta\text{CD}(\text{exciton A}) \quad [8]$$

where $\text{ICD}(\text{A})_{\text{el}}$ = induced CD in A's transitions due to electronic coupling with B's transition's, $\delta\text{CD}(\text{conf A})$ = CD of A due to adopted chiral conformation, and $\delta\text{CD}(\text{exciton A})$ = exciton CD of A interaction with neighbour A molecules.

Special situation (a). When A is a chiral molecule added in enantiomerically pure form, then $\text{ICD}(\text{A})$ = induced

Figure 5 The 'Pfeiffer' ICD of inversion labile $[\text{Fe}(\text{phen})_3]^{2+}$ upon binding to DNA. Following DNA addition, a small ICD is immediately seen due to the preferential association of one enantiomer and electronic perturbation of its CD [*special situations (a) and (b)*]. Therefore, a strong CD evolves more slowly as a result of a shifted diastereomer equilibrium, giving a net excess of one enantiomer.

Figure 6 β -Cyclodextrin (left) and the signs of the CD observed in the transitions of a guest molecule depending on their polarization directions: axially polarized transitions appear with positive ICD, whereas transitions polarized in the plane of the cyclodextrin ring appear with negative ICD. Reproduced with permission from Roger A and Nördén B (1997) *Circular Dichroism and Linear Dichroism*. Oxford: Oxford University Press.

CD in A's transitions due to electronic coupling with B's transition + $\delta\text{CD}(\text{chir})$ of A due to any changed (chiral) conformation of A + $\delta\text{CD}(\text{Abs})$ of A due to any changed absorption property (hypo-/hyperchromism) of A. The third contribution scales directly as the changed absorption, δAbs :

$$\delta\text{CD}(\text{Abs}) = \frac{\delta\text{Abs} \times \text{CD}(\text{A})}{\text{Abs}} \quad [9]$$

Hence if $\text{CD}(\text{A})$ is large, $\delta\text{CD}(\text{Abs})$ will be large, even for small δAbs .

Special situation (b). A is a chiral molecule added as a racemate: then, in addition to the contributions in situation (a),

there is additionally the effect of any enantioselectivity of binding A to B, which adds the following extra term to ICD(A): $+\delta\text{CD}$ of A due to that the enantiomer bound may have changed its absorption properties (hypo/hyperchromism) or conformation.

Special situation (c). A is a chiral molecule subject to inversion. The enantioselective binding to B can then affect the equilibrium between the enantiomers to make the total of A non-racemic (an excess of one enantiomer). Generally, the preferred enantiomer is thermodynamically stabilized. This is the so-called 'Pfeiffer effect'. An example is given by the addition of labile $[\text{Fe}(\text{phen})_3]^{2+}$ to DNA where the observed ICD is comprised of two components. There is an immediate effect according to situation (b) and a slower developing (stronger) Pfeiffer ICD due to an inversion yielding a net excess of the enantiomer in the solution, as shown in Figure 5.

ICD in cyclodextrins

The CD of large, formally rather complicated systems is sometimes as simple as that of much smaller ones, particularly if the system has high symmetry. One such system is a β -cyclodextrin host-guest complex. Cyclodextrins are α -1,4-linked D-glucose oligomers, where α -cyclodextrins have six glucose units and β -systems have seven and so on. Since cyclodextrins have been found to catalyse reactions involving their guests, it is of interest to know the orientation of the guest inside the sugar ring (Figure 6). The CD induced into the

transitions of known polarization of the guest may show that immediately. Most experiments have been conducted using the β -cyclodextrin framework, which has a cavity of the correct size to accommodate a single aromatic molecule such as benzene or naphthalene. Another application of cyclodextrin-induced CD is for the assignment of transitions in C_{2v} or D_{2h} symmetric molecules: ICD of opposite signs corresponds to transitions with mutually perpendicular polarizations.

Inductively coupled plasma mass spectrometry (ICP-MS) combines an ICP with a mass spectrometer. It features a multielemental capability, good precision, a long linear dynamic range, simple spectra, low detection limits and the ability to do rapid isotopic analysis. With such advantages, ICP-MS has found wide application to the analysis of a variety of samples, including water and food, as well as geochemical, environmental and biological samples. However, it has a number of limitations, such as matrix effects, which can be important, and the need to keep the concentration of dissolved solids low to avoid clogging problems. These complicate the analysis by requiring sample pre-treatment and/or more involved calibration strategies. Nonetheless, with the appropriate method development and/or optional accessories, these limitations can be largely circumvented, thereby allowing ICP-MS to be applied to the analysis of virtually any type of sample.

Description of a Basic ICP-MS Instrument

Figure 1 shows a block diagram of an ICP-MS instrument. A 1–2.5 kW Ar ICP is the typical ion source for MS. The ICP is a high-temperature (5000–10 000 K)

electrodeless discharge that is sustained in argon flowing within a torch. In general, the ICP uses samples in solution, which presents the advantages of good control over homogeneity and ease of calibration. A sample solution is delivered to a nebulizer using a peristaltic pump to minimize physical interferences (from, for instance, changes in viscosity). The nebulizer converts this solution into an aerosol that is then carried by the nebulizer gas through a spray chamber where large droplets condense and drain out. The resulting fine aerosol is injected into the heart of the plasma, and undergoes several sequential processes as it moves deeper into the plasma: desolvation, vapourization, atomization and ionization.

In an Ar ICP, the degree of ionization of 52 elements is expected to be $\geq 90\%$. Only three elements (He, F and Ne) which possess a first ionization potential greater than that of Ar would not be ionized and could therefore not be determined by ICP-MS with an Ar ICP. Similarly, the highest degree of double ionization is 10% and occurs only for a few elements. The ICP is therefore an efficient elemental ion source for MS since the majority of elements in the periodic table are singly ionized.

A portion of the plasma (which is typically three sampler orifice diameters wide and two sampler orifice

Figure 1 Schematic representation of a conventional ICP-MS instrument.

Table 1 Typical specifications of ICP-MS instruments

Parameter	Type of instrument	
	Low resolution	High resolution
Resolution	1 amu ^a	300–10 000 amu ^b
Mass range	1–300 amu	1–500 amu
Background level across the mass range	<2–50 cps	≪0.1 cps

^aPeak width at 10% from the peak maximum.^b10% valley between two adjacent peaks.

diameters deep) is sampled from the central channel of the plasma, and extracted through a differentially pumped interface (through two water-cooled metal cones with orifice diameter ~ 1 mm, the sampler and the skimmer), which is maintained at approximately 1 torr using a mechanical roughing pump. This portion is then transmitted into the mass spectrometer where ions are separated according to their mass-to-charge ratios (m/z) and counted.

Two different categories of ICP-MS instruments are currently commercially available: low-resolution instruments, using either a quadrupole or a time-of-flight (TOF) tube to achieve ion separation, and double-focusing high-resolution instruments that use an electrostatic and a magnetic analyser in series. Both the quadrupole-based and the double-focusing instruments allow a sequential multi-element measurement, whereas TOF-ICP-MS allows simultaneous multielement detection.

Selected specifications for these two categories are summarized in **Table 1**. Aside from resolution, one distinctive feature of high-resolution instruments is the negligible background which is observed across the mass range. This results from the curved path that the ion beam must follow, which efficiently prevents photons from reaching the detector, as well as from the operating pressure that is considerably lower than that of low-resolution instruments, and thereby minimizes collisional processes in the ion beam.

Capabilities of ICP-MS

Table 2 shows that ICP-MS has numerous advantageous features: large linear dynamic range, advantage of working with samples in solution, good precision, and low detection limits. The linear dynamic range for many elements is such that major, minor and trace levels may all be determined at once. Furthermore, the multi-element capability of ICP-MS allows the determination of, for instance, 70 elements in less than 2 min, using less than 2 mL of solution at an uptake rate of 1 mL min⁻¹. Detection limits are typically ≤ 1 ng L⁻¹ for most elements with all low-resolution instruments, and even lower

Table 2 Attributes of ICP-MS instruments

Feature	Type of instrument	
	Low resolution	High resolution
Orders of linear dynamic range	5–9	9
Short-term precision for 10 repeats (%)	1–3	2
Sensitivity (Mcps (10 ⁶ counts per second)/ppm)	1–30	20 at $R = 300$
Detection limit ^a (ng/L)	<1–10	1 at $R = 3\ 000$ <0.01–1 ($R = 300$ –500)

^aBased on three times the standard deviation of the blank.

with high-resolution instruments. This difference arises from the lower background typically obtained on high-resolution instruments, as well as the higher reliability in peak hopping which results from the flat-top shape of the peaks observed in high resolution. Sensitivity is similar on all instruments in low resolution, but is degraded by an increase in resolution because this is typically achieved by decreasing the slit width of the entrance and exit slits on double-focusing instruments, which in turn leads to a reduction in ion transmission.

In any case, since specific isotopes are detected, isotope ratios can be measured. Also, calibration by the very accurate isotope dilution analysis method can be done (where internal standardization is essentially carried out using an enriched isotope of the analyte). The flat-top peaks, which are typical of high-resolution instruments, should allow the measurement of ratios with better precision than that achievable with quadrupole-based instruments. However, because these mass spectrometers cannot be scanned as fast as quadrupoles, the resulting precision can be degraded compared to that obtained with quadrupole MS. The best precision is expected with TOF instruments since they allow the simultaneous detection of all masses.

All these features explain why even the basic ICP-MS instrument described so far is being applied to analyses in a variety of areas. For instance, **Table 3** shows that ICP-MS is widely used for environmental, clinical and geochemical studies, with appropriate sample preparation procedures. These are required not only to put solid samples in solution, but also to avoid or circumvent limitations of ICP-MS by, for instance, removing sources of interference.

Limitations of ICP-MS

Table 2 indicates that, whatever the resolution, detection limits vary with the element being determined. There are, indeed, several factors affecting detection limits in ICP-MS. The degree of ionization of the analyte, the

Table 3 Examples of applications of ICP-MS

<i>General category</i>	<i>Samples</i>	<i>Sample pre-treatment</i>
Water	Sea water, industrial waste water, pore water, river water, fresh water, rain, ground water, lake water, spring water, snow, tap water, high-purity water	Filtration and any of the following: acidification and dilution ion exchange separation to remove interferences and/or preconcentrate analytes pre-concentration by evaporation
Environmental	Soil, dust, leaves, sediments, sewage, industrial effluents, paint, atmospheric aerosols, suspended particulate matter, tobacco smoke condensate, domestic sludge, glass, spent nuclear fuel, leachates of high-activity waste, rocks, metals, ores, alloys, ceramic materials	Crushing or grinding, and either digestion with high-purity acids or fusion and dissolution, followed by dilution
Food	Prawn parts, wheat flour, spinach, cabbage, wine, mussels, beef kidney, milk	Digestion with high-purity acids followed by dilution
Biological	Faecal material, urine, human serum, plasma, red blood cells, whole blood, cerebrospinal fluids	Dilution or drying, ashing and/or digestion with high-purity acids followed by dilution or extraction
Organic	Crude oil, gasoline	Extraction into aqueous acidic solution

natural abundance of the isotope that is used for the determination of a particular element, spectroscopic interferences from the background and/or the sample matrix, and mass discrimination are the most notorious sources of degradation. Obviously, if an element is only 50% ionized in the plasma, then its detection limit will be reduced by a factor of 2 compared to an element which is completely ionized. Similarly, if only one isotope of a multi-isotope element is detected, the resulting detection limit will be less than that of a monoisotopic element.

Furthermore, the sample introduction system is the Achilles' heel of all ICP-based instruments. Indeed, only about 2% of the sample solution actually reaches the plasma with a conventional system (composed of a pneumatic nebulizer and spray chamber, as shown in **Figure 1**), most of it going down the drain. This means, therefore, that only a small fraction of the total possible signal is obtained.

As mentioned earlier, because the mass spectrum is simple, the likelihood of spectroscopic interferences is reduced, particularly with high-resolution instruments. However, when they occur, the number of alternative lines is small (there are indeed a number of monoisotopic elements). One example of an isobaric interference that cannot be resolved even at high resolution is that of $^{40}\text{Ar}^+$ on $^{40}\text{Ca}^+$, the major isotope of Ca. Other severe interferences arise from Ar-containing polyatomic ions as well as oxides of matrix elements. Several of these can be resolved at higher resolution but with a concurrent sacrifice in sensitivity and detection limits. On low-resolution instruments, a 'cold plasma', where the ICP is operated at lower power and higher nebulizer gas flow rate, can be used to reduce important interferences from the background but, again, a lower sensitivity concurrently results across the mass range.

Mass discrimination is most important for quadrupole-based instruments where the transmission of ions is not uniform over the mass range. In particular, the transmission of light ions is reduced compared to heavier ions. Another parameter which may also affect the detection capability of ICP-MS is the plasma sampling position, which may not be optimal for all the analytes being determined simultaneously. This position is indeed important to maximize the density of analyte ions extracted from the ICP. Even the chemical form (i.e. speciation) of an element in solution may influence where it undergoes the various processes (desolvation, vapourization, etc) in the plasma, ultimately determining where the maximum ion density will be.

The sampling process itself is the source of another limitation: because part of the plasma passes through a small orifice, this orifice can become clogged by dissolved solids. The maximum concentration of dissolved solids which can be tolerated on a continuous basis is 0.2%. Finally, even if this level is kept reasonably low, effects of concomitant elements (also called matrix effects) can occur, whereby the analyte signal is either suppressed or enhanced by the presence of other elements. Some trends have been observed and partly explained. For example, a heavy matrix element will in general induce a more important suppression than a light matrix element on quadrupole-based instruments because of space-charge effects. However, these matrix effects are still largely unpredictable, which complicates the calibration process for samples that do not possess a relatively simple matrix. Whenever possible, a simple dilution of the sample is recommended to minimize the effects of concomitant elements, since they depend on the absolute amount of concomitant element.

The various calibration strategies available with ICP-MS are summarized in **Table 4**, along with implications

Table 4 Calibration strategies in ICP-MS

<i>Method</i>	<i>Requirements</i>	<i>Quality of results</i>
External calibration	One isotope free of spectroscopic interference per analyte Matrix matching and/or correction for drift (using internal standardization or frequent calibration)	Good accuracy and precision
Standard additions	One isotope free of spectroscopic interference per analyte May require a correction for drift (using internal standardization)	Good accuracy and precision
Isotope dilution	Two isotopes free of spectroscopic interference per analyte Good equilibrium between isotopic spike and sample	High accuracy and precision

of the above-mentioned limitations. (More elaborate chemometric calibration procedures have also been developed by a few groups.) In general, unless the sample matrix is simple, internal standardization (or frequent calibration) will be required for quantitative analysis using external calibration with a series of standard solutions. The choice of the internal standard(s) depends on the instrument, the sample, etc. For the best results, an element with properties similar to that of the analyte (so that it will behave similarly in ICP-MS) is needed, so several internal standards may be required for a multi-elemental analysis spanning the entire mass range.

The method of standard additions efficiently compensates for matrix effects but not for drift. If the latter is also present (for instance because of gradual clogging), internal standardization may also be required. The best method to compensate for both matrix effects and drift is isotope dilution analysis. However, it is only applicable to elements with at least two isotopes (stable and/or long-lived radioactive) free of spectroscopic interferences. Because of mass discrimination, this normally standardless technique requires a prior determination of mass bias using standards of known isotopic composition in order to correct the measured isotope ratios for mass discrimination.

Accessories Available to Expand the Capabilities of ICP-MS

Major modifications can be made to the ICP-MS instrument, such as adding one or two quadrupoles, and operating one quadrupole in an RF-only mode so that it can serve as a cell where gas-phase collisions are performed to break polyatomic ions. However, several more or less expensive accessories that can be readily interfaced to ICP-MS are available to circumvent one or more of the above-mentioned limitations. The most frequently used are summarized in **Table 5**.

The sample introduction system can simply be replaced by a high-efficiency one, such as an ultrasonic nebulizer coupled to a desolvation system. Analyte

transport efficiencies of 10–20% are typically achieved using such a system. Other high-performance nebulization systems include direct injection nebulization, which introduces 100% of the sample directly into the plasma (i.e. no spray chamber is needed), thermospray, hydraulic high-pressure nebulization and monodisperse dried microparticulate injection.

The characteristics of the plasma can also be modified by adding another gas to argon. For instance, an addition of O₂ to the plasma is beneficial for the analysis of organic solutions as it prevents the deposition of soot on the interface. The addition of gases with a higher thermal conductivity than argon (such as H₂) can be used to enhance sensitivity (by improving the ionization efficiency), reduce and/or eliminate spectroscopic and non-spectroscopic interferences, and reduce mass discrimination.

Table 5 demonstrates that various approaches can be used with a basic ICP-MS instrument to overcome spectroscopic interferences. Many of these approaches consist in separating the problematic element(s) from the analyte during sample preparation (by extraction, chelation, selective precipitation, etc). Although they can be quite effective at reducing both spectroscopic and non-spectroscopic interferences (if the source of the latter is also removed during sample processing), they are nonetheless time-consuming and increase the likelihood of contamination.

Most of these separations can be carried out on-line with ICP-MS using a flow injection manifold. A big advantage of this approach is that all the chemistry is done in a closed system, often on a reduced scale, thereby reducing sources of contamination, as well as sample and reagent consumption. Chemical vapourization approaches can also selectively isolate the analyte and transform it into a volatile species, in either continuous or flow injection fashion. Alternatively, selected species of the analyte can be determined by coupling gas, liquid or supercritical chromatography, or capillary electrophoresis, to ICP-MS.

As mentioned earlier, solid samples must first be put in solution for analysis by conventional ICP-MS, using digestion, fusion, dry-chlorination, etc, which all introduce potential sources of contamination. Slurry nebulization, which

Table 5 Options widely used to enhance the capabilities of ICP-MS

<i>Method</i>	<i>Advantages</i>	<i>Disadvantages</i>	<i>Examples of applications</i>
Ultrasonic nebulization with desolvation	High sample introduction efficiency Reduction of oxides through removal of solvent	Prone to memory effects Cone blockage and matrix effects from concentrated matrix	Analysis of river water, lake water, rain and other samples with simple matrix
Mixed-gas plasmas	Reduced spectroscopic interferences Reduced matrix effects	Higher incidence of torch melting	Analysis of fuel oil, vegetable oil, sea water, urine, slurries
Flow injection analysis	Reduced memory effects Increased sample throughput Reduction of matrix effects Enhancement of sensitivity On-line pre-treatment chemistry	System must be modified and optimized for each type of application	Analysis of samples with high level of dissolved solids (sea water, brines, urine, etc), concentrated acids, volume-limited samples
Chromatographic techniques	Speciation of aqueous and gaseous samples Separation of analyte from matrix	Different interfaces required for different techniques Chromatographic resolution dependent on interface to ICP	Determination of toxic and non-toxic species in biological materials, food, environmental samples
Chemical vapour generation	Selective separation of analyte from matrix	Different chemistries and/or conditions required for different analytes	Determination of hydride-forming elements and/or species in a variety of samples
Electrothermal vapourization	Up to 100% sample introduction efficiency Small sample volume Direct solid analysis	Only one or a few elements can be determined at once Matrix modifiers often required to prevent loss of analyte	Analysis of waters, biological materials, food, volume-limited samples
Slurry nebulization	<i>In situ</i> pre-treatment of sample Up to 100% sample introduction efficiency Eliminates digestion and fusion steps Calibration with aqueous standards	No available sample blanks Efficiency of calibration dependent on particle size and sample type	Analysis of rocks, soils, hard-to-dissolve samples (such as coal)
Laser ablation	Direct solid analysis <i>In situ</i> analysis of interstitial fluid Microscopic profiling of solid samples	Limited number of reference materials available for calibration No available sample blanks	Analysis of geological samples, ceramic materials, glass

simply consists in grinding the sample and suspending it in a suitable dispersing agent, can significantly reduce these contaminations. Alternatively, solids can be analysed directly using various techniques coupled to ICP-MS: electrothermal vapourization, laser ablation (as well as arc/spark ablation), direct sample insertion, fluidized bed introduction,

etc. These techniques are even more interesting for samples which are difficult to dissolve. Some of them (electrothermal vapourization and direct sample insertion) can also be used for the analysis of solutions.

All these approaches enhance the capabilities of ICP-MS but complicate the optimization process. The full potential

of some of them (such as ablation techniques, flow injection, etc), which generate short, transient signals, will be better realized if an instrument allowing simultaneous multi-element detection (such as TOF) is used. In any case, no single method can be used for the direct analysis of every sample. Some method development is therefore required for each new sample type, whether ICP-MS is used with or without one or more of the available options.

Industrial Applications of IR and Raman Spectroscopy

AS Gilbert, Beckenham, Kent, UK

This article is reproduced from the previous edition, volume 2, pp 881–893, © 1999, Elsevier Ltd.

Extensive use is made of IR and Raman spectroscopy in industry, because these techniques have the capacity to provide information at the chemical molecular level on virtually any material of interest, be it solid, liquid or gas. They are well understood, can be easily applied and results can be obtained quickly and cheaply. Instruments utilized range from simple single-channel IR filterometers to sophisticated computerized interferometers and spectrographs supported by flexible data handling software. In addition to process functions they are employed in quality assurance and troubleshooting in the quality control (QC) environment and in analysis (both qualitative and quantitative) in research and development (R&D). Areas of application are pre-eminently in the chemical, oil and gas, plastics and pharmaceutical industries, but there is also considerable use in materials industries, mining, agriculture and food processing.

Applications of near-infrared (NIR) spectroscopy will not be described in this article but can be found elsewhere in the Encyclopedia. The examples of IR and Raman spectroscopy given below represent, of course, only a tiny fraction of what is done in industry and are necessarily a rather arbitrary selection.

Brief History

With the introduction of commercially available, automatically recording, spectrometers during World War 2, IR spectroscopy began to be utilized in industrial laboratories and by the 1960s dedicated instruments had reached the factory floor. The advent of FT-IR machines designed specifically for the analytical market and a much wider range of accessories then saw a considerable expansion in use from the early 1980s onwards, particularly in QC and development laboratories.

Expense and technical difficulty meant that it was not until the 1970s that anything more than a handful of Raman spectrometers were employed in industry. Take-up, even by industrial research laboratories, continued to be slow until the arrival of relatively cheap computerized spectrographs, FT-Raman and advanced methods of sampling during the 1980s.

The Special Conditions of the Industrial Environment

Employment of instrumentation is much the same in industrial research laboratories as it is in academic institutions, although of course the aims of the former are necessarily more focused to particular objectives. But elsewhere in industry both time and money, within the constraints of safety, are of prime importance and the usefulness of information provided by any technique must be judged primarily by these criteria. The nearer the production line, the greater is the degree of rigour with which these criteria are applied. Rapid measurement, high degree of automation and reliability, all at minimum cost, are therefore demanded of manufacturers of spectroscopic equipment.

A major cost element of any activity is personnel. This predicates dedicated operation with as much 'black box' control of instrumentation as possible and incorporating robust protocols.

The factors described above tend inevitably to induce conservative attitudes in industrial practitioners so that it is important that any technique and its particular area of application be well understood, widely accepted and validated by longtime usage. The activities of organizations such as ASTM (American Society for Testing Materials) which have overseen the establishment of standard procedures for many common but specific spectroscopic measurements have been highly important in cementing acceptance of such methodology. Scientific forums that bring together both industrial and academic workers are extremely helpful in circulating ideas. The long-standing British-based IRDG (Infrared and Raman Discussion Group) is a good example of a body that organizes regular lecture meetings, often at industrial locations.

Instrumentation

As vibrational spectroscopy was originally a research technique, many spectrometers used in industry in the past have been derivatives of research-oriented machines. However, most equipment is now produced for the 'analytical' market so this relationship (even for Raman

spectrometers) has been turned around and now many so-called 'research' machines are just the standard 'analytical' instrument with add-on features. Outside R&D most instrumentation is designed for dedication to specific tasks and a great many IR machines sold are single-channel filterometers.

Such instruments are non-dispersive and utilize a narrow bandpass filter to monitor one compound of interest, commonly carbon dioxide or carbon monoxide, in a process environment. The bandwidth of the filter is closely matched to the bandwidth (for carbon dioxide the unresolved envelope of a number of rotational sidebands) of the analyte and a reference signal is obtained from another filter which passes radiation from a transparent area of the spectrum.

Full-spectrum machines are now, in the case of IR, mostly interferometers. The benefits of full computerization, high sensitivity, ease of operation and 'quantitative analysis' software packages have rendered the classical dispersive spectrometers obsolete. Portable operating software has meant that industry standard PCs and workstations can be used as 'front ends' on most if not all commercial instruments now sold.

Until relatively recently, Raman spectroscopy was not generally suited to industrial use with the exception of specific problems in R&D. Although the classical double grating dispersive scanning spectrometers could be computerized, they were slow and often subject to problems such as sample fluorescence. This has been changed by the advent first of simple and rugged spectrographs with multichannel (usually charge-coupled device (CCD)) detectors and second of FT-Raman

modules that can be 'bolted on' to standard FT-IR machines. Spectrographs have addressed the speed problem while FT-Raman, which uses near-IR excitation, is not troubled by fluorescence.

Sampling Methods

Many of the sampling accessories now available for vibrational spectroscopy were developed for specific industrial use or with industry in mind. Some of the most important more recent developments have been in the production of fibre-optic attachments that can allow data to be obtained *in situ* with remote spectrometers. Optical fibres are available for the Raman region but though suitable materials (e.g. chalcogenides) that are transparent in parts of the mid-IR region can now be manufactured, fibre-optic probes in this region are somewhat limited in usefulness. **Figure 1** demonstrates the quality of a Raman spectrum that can be obtained from inside a container, in this example an amber vial holding acetone. The flexible fibre-optic probe was merely placed on the outside of the glass so that sampling was completely non-invasive.

Raman microscopy imaging, the spectroscopic mapping of a sample placed on a computer-controlled motorized stage, has applications in many areas. A TV attachment gives visual guidance to the operator for location of an area of interest and real-time spectra are produced. A particular application, in this example from the pharmaceutical industry, is the examination of powders, particles down to 1 μm (or less) being distinguished.

Figure 1 The Raman spectrum of acetone contained within an amber vial. A HoloProbe (Kaiser Optical Systems, USA) fibre-optic probe transmitting a visible excitation line at 532 nm was utilized. The length of the fibre optic can be 100 m or more while, by changing attachments, the head can collect the Raman signal from distances of between about 0.03 and 40 cm.

Figure 2 Raman microscope image and associated spectra of a pharmaceutical powder. (a) Raman image that gives the relative importance of each compound (A, B, C), and spectra of (b) compound A, (c) compound B and (d) compound C.

Figure 3 IR stack plot of the progress of a reaction of a β -lactam reactant A giving intermediate B and product C.

This is an order of magnitude better than IR microscopy. **Figure 2a** illustrates a colour-coded Raman map that offers chemical information on the disposition of different components of a mixture, the three distinct spectra

shown in **Figures 2b, c and d** being obtained by 'specifying' three particular points in the image. The Raman image analysis software can also be used to assess particle size distribution.

Figure 4 IR chromatogram of the first 40 min of a GC-IR separation of aromatic components in a sample of gasoline. The peaks represent the total integrated absorbance intensity in the region 900–600 cm^{-1} . Copyright 1995 American Chemical Society.

Attenuated total reflection (ATR) probes can be used to follow chemical reactions *in situ*. An example is the react-IR (Applied Systems) instrument. Although ZnSe is commonly used as the optical element in ATR, it is not robust enough to deal with certain chemical reactions, e.g. bromination, so a diamond tip is utilized instead. **Figure 3** shows the spectrum of a fused-ring β -lactam which yields a carbonyl band at 1785 cm^{-1} . This can be seen reacting via an intermediate to give a less strained β -lactam with a carbonyl vibration near 1760 cm^{-1} .

The production of potassium bromide discs for IR spectroscopy has never been automated, although at least one scheme has indicated the possibility. When dispersive spectrometers were used, this did not matter so much as spectrum acquisition was of the same order of duration as sample preparation, but FT-IR machines are much more rapid. Thus diffuse reflectance has recently become a very popular technique for monitoring the IR spectra of organic compounds that are soluble in volatile solvents as it only requires the placing of a drop of solution on a small layer of ground alkali metal halide powder.

For dealing with large numbers of compounds from chromatographic or other types of separation, the so-called ‘hyphenated’ methods are used. The most popular are the combinations with gas chromatography (GC-IR), thermogravimetry (TG-IR) and gel-permeation

Figure 5 FT-IR spectra of coal tar fractions examined as either (a) a film or (b, c) KBr discs. Reprinted from Diez MA, Alvarez R, Gonzalez AI, Menendez R, Moinelo SR, and Bermejo J (1994) *Fuel* 73: 139–142, Copyright 1994, with permission from Elsevier Science.

chromatography (GPC-IR). **Figure 4** is the IR chromatogram of part of a GC separation of fractions in a typical gasoline (petrol). One of the aims was to detect aromatic components the levels of which are strictly controlled by various ‘clean fuel’ legislations (in the USA and elsewhere). Only IR absorption from the 900–600 cm^{-1} region has been utilized in this example, this being the region of the characteristic C–H out-of-plane bending modes of aromatic compounds. The level of benzene in this sample, which was of the order of 0.02% by mass, could be determined by the GC-IR method to an accuracy of within 1% of the measured value.

Data Handling

Data transfer to computer networks such as LIMS (laboratory information management systems) is now straightforward using the JCAMP world standard data format and modern operational software for vibrational spectrometers is usually set up for this. Sophisticated quantitative analysis packages are generally available for use in analytical laboratories and designed for largely ‘black box’ operation, which is obviously attractive to industry. Some of the chemometrics methodology (e.g. partial least squares (PLS)) behind the software still

Figure 6 FT-IR spectra of forms (a) I and (b) II of lamivudine as Nujol mulls. Resolution, 2 cm^{-1} . Reproduced with permission from Harris RK, Yeung RR, Lamont RB, Lancaster RW, Lynn SM, and Staniforth SE (1997) *Journal of the Chemical Society, Perkin Transactions 2*: 2653–2659.

draws criticism from some quarters, which might cause problems when regulatory authorities are involved.

Research and Development

Many substances of interest to industry are highly complex but vibrational spectra can still provide useful insights into their nature. **Figures 5a, b and c** show the IR spectra of a series of coal tar fractions which were obtained by carbonization of a wet charge of coal in an

industrial coke oven at a mean flue temperature of 1220°C . The fractions are principally composed of complex multi-ring aromatics. While the spectra clearly yield many bands characteristic of aromatic systems, for instance the substitution sensitive C–H out-of-plane bending vibrations below 1000 cm^{-1} , other functionalities are obviously present, such as O–H and N–H. Interestingly, spectrum (b) shows a band at about 2220 cm^{-1} (just below the negative, instrument-uncompensated, CO_2 peak at about 2300 cm^{-1}) indicating nitrile, possibly from a naphthocarbonitrile.

Figure 7 Part of the FT-IR/ATR spectrum of polystyrene beads with attached compound (see text). Courtesy of Perkin-Elmer Ltd.

Figure 8 Part of the FT-IR/ATR spectrum of Tentagel beads with attached compound (see text). Courtesy of Perkin-Elmer Ltd.

Vibrational bands are very sensitive to intermolecular effects, thus different crystal modifications of a single compound usually yield discrete spectra. The occurrence of differing crystal forms is known as polymorphism and

is of interest as the physical properties are dissimilar. This can have considerable ramifications in the pharmaceutical industry as the dissolution and absorption rates of polymorphic forms of a drug may differ

Figure 9 Automated headspace analyser. A Model HR640 MSL (Instruments SA) Raman spectrograph with an Astromed CCD multichannel detector is utilized. Laser excitation at 488 nm. Courtesy of Hobbs KW, Glaxo-Wellcome plc.

significantly, with serious consequences for therapeutic action and patient tolerance.

Figures 6a and b display the IR spectra of forms I and II, respectively, of lamivudine, a 1,3-oxathiolane nucleoside which has anti-viral activity:

The two forms are not strict polymorphs because I is a hydrate (one H₂O per five lamivudines), but have different crystal structures and spectra. The O–H stretching mode from the hydrate water in I can clearly be seen at

3545 cm⁻¹. The strong bands just below 3000 cm⁻¹ are from the hydrocarbon mulling agent used to prepare the material for spectroscopic measurement.

Combinatorial Chemistry

Schemes for combinatorial syntheses of compounds, particularly candidate pharmaceuticals, now attract great interest because of the potential for greatly speeding up the discovery of new drug molecules. They are sometimes based on carrying out chemical reactions on solid artifacts, the starting material, intermediates and final product being attached to the solid phase; on completion the product is cleaved away into solution. Typically the solid substrate is a mass of small (of the order of tens or 100 μm or so) porous beads made of polymer or silica resin. They are suspended, by agitation, in reactant solution, which is removed on completion by filtration.

Figure 10 Raman spectra of various mixtures of nitrogen and oxygen obtained with the spectrograph in **Figure 9**. For the sake of clarity the spectra have been vertically displaced from one another. The N_2 peak is on the right. Band intensity is essentially from the pure vibrational mode. The rotational-vibrational side bands form weak overlapped 'wings' on either side of the main peaks. Reproduced with permission of the Society of Photo-Optical Instrumentation Engineers (SPIE) from Gilbert AS, Hobbs KW, Reeves AH, and Jobson PP (1994) Automated headspace analysis for quality assurance of pharmaceutical vials by laser Raman spectroscopy. *Proceedings of the SPIE – Society of Photo-Optical Instrumentation Engineers* 2248: 391–398.

The beads are washed with solvent between stages of synthesis.

A considerable challenge is thereby presented to analytical technology if the progress of the reaction is to be monitored without going through the time-consuming business of analyte removal. Mass spectrometry cannot be used and NMR only with difficulty because of sensitivity problems. However, IR spectroscopy is fairly easy to utilize, either by diffuse reflectance or, as in the cases below of two drug intermediates, by ATR sampling methods. **Figure 7** is the spectrum of

attached to polystyrene beads, the carbonyl stretching band being clearly seen at 1690 cm^{-1} . There is little interference with this highly characteristic band from the

Figure 11 IR difference spectra, CZ–FZ, using FZ (bottom) as reference. Samples were 2 mm thick. Carbon–oxygen complex bands are indicated by arrows. See text for definition of CZ and FZ. polymer. The silica resin (Tentagel) presents a greater problem, although as shown in **Figure 8**, a number of bands from attached

can still be observed, e.g. the carbonyl vibration at 1741 cm^{-1} . The very strong band near 1100 cm^{-1} is, of course, from Si–O stretching. These spectra were obtained from a small cluster of beads, but it is possible using microscopy techniques to examine a single bead at a time.

Quality Assurance

Pharmaceuticals

As visible radiation is unaffected by passage through clear, colourless glass (apart from inducing minor fluorescence), Raman spectroscopy can be used to monitor gases contained within the headspace of sealed vials.

Figure 14 IR transmission spectrum of traces of water in 1,2-dichloroethane. Note that the scale is in microns, which can be converted to wavenumbers by taking the reciprocal and multiplying by 10 000; e.g. 2.7 μm is equivalent to 3703.7 cm⁻¹. Reproduced with permission of the Royal Society of Chemistry from Bruce SH and Dhaliwal HK (1991) On-line moisture analysis by IR. In: Davies AMC and Creaser CS (eds.) *Analytical Applications of Spectroscopy II*, pp. 46–52. Cambridge: Royal Society of Chemistry.

Figure 9 is a photograph of equipment that performs automated headspace analysis of vials (1 mm thick borosilicate glass) containing the pharmaceutical product Flolan (sodium prostacyclin) that is freeze-dried and sealed (with rubber stoppers secured by aluminium caps) under nitrogen. The product, although buffered, is highly sensitive to degradation by ingress of carbon dioxide if admission of air occurs, leading to a severe reduction in shelf-life. Any leakage, which might very occasionally occur before final capping, is detectable, however, by assaying for oxygen with the nitrogen as reference, using the Raman bands from the stretching modes of these molecules at about 1550 and 2330 cm⁻¹, respectively (**Figure 10**).

The analyser is built around a spectrograph with a CCD multichannel detector and the spectra are generated by laser radiation at 488 nm from an argon ion laser. Oxygen percentages can be measured to $\pm 0.3\%$ O₂ ($\pm$ one standard deviation) for a measurement time of 1 s. Mechanical restrictions mean that sample throughput is slower than this, but still sufficiently fast that total batch inspection can be performed.

Semiconductors

An important requirement in the semiconductor industry is to be able to measure various undesirable impurities in silicon wafers which can interfere with their electrical

Figure 15 Diagram of process ATR cell for on-line moisture analysis. Reproduced with permission of the Royal Society of Chemistry from Bruce SH and Dhaliwal HK (1991) On-line moisture analysis by IR. properties. Two significant impurities are oxygen which can incorporate interstitially and carbon which can substitute into lattice sites. Although pure silicon itself yields a very weak IR spectrum, fairly thick samples can be examined in transmission and therefore trace levels of the impurities can be detected and routinely quantified. Standard methods for IR spectroscopic determination of the impurities have been published by ASTM.

Oxygen forms Si–O–Si bonds which yield a characteristic band at 515 cm^{-1} from Si–O–Si deformation (a stronger band from Si–O stretching occurs at 1107 cm^{-1}). Carbon can be detected by the Si–C stretching band at 607 cm^{-1} .

Figure 11 shows some room temperature difference spectra of CZ silicon using FZ silicon as reference (CZ and FZ refer to two different methods of growing silicon crystals, Czochralski process and float zone, respectively). It is interesting to note that the high-carbon CZ sample contains so much oxygen that weak bands from carbon–oxygen complexes are observed. Quantitative determination of carbon and oxygen is possible down to low ppm levels.

Dedicated FT-IR spectrometers are extensively employed to measure the thickness of epitaxial layers on silicon wafers. The measurements are made in reflectance mode and what is observed is not the spectrum but the interference pattern from multiple back and forth reflections within the layer. The regular distance between the maxima (or minima) gives the thickness and the fringes can be directly perceived from the interferogram as two ‘side-bursts’ on either side of the centre.

Process Control

Analysis of edible oils and fats is an important activity in the food industry. Quantification of *cis* and *trans* unsaturation levels is one part of this activity. Many edible oils are found in the *cis* form and are liquids. They are often partially hydrogenated to improve stability and hardness (e.g. for ‘healthy’ alternatives to butter), but in the process some *cis* bonds are converted to *trans*. Unfortunately, *trans* unsaturated fatty acids have been implicated in heart disease, but they can easily be detected by the presence of the characteristic out-of-plane olefinic C–H bending vibration at $980\text{--}965\text{ cm}^{-1}$. *Cis* bonds do not interfere as they yield the corresponding vibrational mode at $730\text{--}650\text{ cm}^{-1}$.

The standard IR spectroscopic procedure (American Oil Chemists Society) involves dissolution in carbon disulfide with chemical modification if *trans* levels are <15%. Peak height only is used for calculation and the overall procedure is slow. By taking advantage of modern multivariate chemometric methods, a more rapid and

convenient means of analysis has been developed utilizing a heated flow cell (thermostated to $80 \pm 0.2^\circ\text{C}$) to analyse the neat sample in its liquid state. **Figure 12** is the IR spectrum of the *trans* region for a series of calibration standards and **Figure 13** is a plot comparing measured values by the IR method with gas chromatography,

Figure 19 FT-IR spectra of various concentrations of oleamide in molten low-density polyethylene. Reproduced with permission of the Society of Photo-Optical Instrumentation Engineers from Stengler RK and Weis G (1992) Infrared process control on molten polymers using a high pressure, high temperature flow cell. *Proceedings of the SPIE – Society of Photo-Optical Instrumentation Engineers* 1681: 33–38.

demonstrating high correlation between the two techniques. Calculation for the IR procedure is carried out by the PLS method using multiple spectroscopic points and is thus very 'black box'. The sample measurement time is claimed to be 2 min, sufficiently rapid, therefore, for process monitoring.

A mundane but very common requirement is the on-line measurement of the water content of industrial solvents and feedstocks in process streams. Chemical methods (e.g. Karl Fischer) are not suited to continuous monitoring. Relatively high levels ($>0.1\%$) can be dealt with using NIR methodology, but for very low levels the much stronger (fundamental) O–H stretching bands in the mid-IR region need to be observed. **Figure 14** shows the IR spectrum of traces of water in 1,2-dichloroethane (ethylene dichloride, EDC). Because of the low concentration there is no significant hydrogen bonding between water molecules so that the 'free' asymmetric and symmetric stretching modes appear at 3685 and 3595 cm^{-1} , respectively.

EDC is the feedstock for the manufacture of PVC, being first cracked in a furnace to produce vinyl chloride followed by polymerization. The moisture measurement is usually done in the transmission mode, with a pathlength of around 2 mm, and as there are no other bands in the O–H stretching region a simple IR filterometer can be used. In other cases where the pathlength is too restrictive, for instance if the solvent/feedstock is too viscous, an ATR method can be employed instead. **Figure 15** shows an on-line ruggedized (150 psig , 150°C) ATR cell for this purpose (Servomex, UK) which can be fitted with a variety of IR crystals (for chemical compatibility) and adjusted to give the requisite effective pathlength.

The high sensitivity of FT-IR to many small gas molecules can be exploited to monitor flue gases. **Figure 16** shows the make-up of exhaust gas from a coal-fired boiler. To see the minor components it is necessary to expand the spectral scale as in **Figure 17**. Of importance are obviously the levels of the acid gases, NO and (unburned) hydrocarbons, which can all be measured at ppm levels.

Most industrial polymers contain additives which are there as stabilizers (e.g. cross-linkers, antioxidants) or property modifiers (e.g. slip agents). The diagram of a system (Automatik, Germany) for molten polymer process control using FT-IR to monitor additives on-line is given in **Figure 18**. The flow cell can withstand high pressures (300 bar) and temperatures (400°C) and has an adjustable pathlength. The spectrum shown in **Figure 19** is of various amounts of the slip agent oleamide in low-density polyethylene, the monitored band being the amide carbonyl stretch near 1715 cm^{-1} .

Conclusion

The wide application of vibrational spectroscopy to industrial problems is long established and its use is growing, as evidenced by steadily increasing sales of instrumentation. In many instances other techniques can do the same job but are either less sensitive or slower or more expensive, or are ruled out through other circumstances. In certain cases vibrational spectroscopy may be the only method practicable, such as in the semiconductor applications described above.

The fact that vibrational spectroscopy is amenable to almost any chemical substance is responsible for its

general utility, but this 'non-specificity' can be a weakness where it is necessary to 'pick out' one component from a background. There are one or two special techniques in Raman spectroscopy where this can be done (e.g. resonance Raman and surface-enhanced Raman spectroscopy), but they are not of general applicability.

A particular strength compared with other main-line analytical techniques is in the monitoring of gases from the points of view of both the sensitivity of IR spectroscopy and the non-invasive capability of Raman spectroscopy, coupled with the capacity of both techniques for remote viewing.

V	barrier height
σ_d^{inc}	incoherent cross section of d th atom
τ	average time between jumps
ω	energy transfer

Inelastic neutron scattering (INS) spectroscopy was pioneered in the 1950s by the American physicist Bertram Brockhouse. So it is not surprising that most of the early applications were physics based; particularly the determination of phonon dispersion curves of metals which are critical to the understanding of their thermodynamic properties. However, like many other spectroscopic methods, of which nuclear magnetic resonance is probably the best example, the use of the technique has greatly broadened, and it is now used by researchers in virtually any field that involves the condensed state. The wide energy (or, equivalently, timescale) range available to INS means that different kinds of motion can be probed in the same system, although not usually simultaneously. The applications span from biology through to materials science and to engineering, in addition to physics and chemistry. Particularly active areas include: catalysis, polymers, magnetism, hydrogen-in-metals, hydrogen bonding, glasses, geology and quantum fluids.

Coherent and Incoherent Scattering

Experimentally, the quantity that is usually measured is the scattering function, $S(Q, \omega)$ [Q is the momentum transfer ($\text{\AA}^{-1}$) and ω the energy transfer (meV)]. The scattering can be coherent, $S^{\text{coh}}(Q, \omega)$, or incoherent, $S^{\text{inc}}(Q, \omega)$. The definition of $S^{\text{coh}}(Q, \omega)$ involves the correlation between the positions of different nuclei at different times and thus gives interference effects. This gives information on collective motions in the sample. $S^{\text{inc}}(Q, \omega)$ only involves the correlation between the position of the same nucleus, so there are no interference effects, and the motions of a single particle are probed. This is a powerful method for studying the local environment of the scattering atom.

Whether the scattering is coherent or incoherent depends on the relative size of the coherent and incoherent scattering cross sections of the scattering nuclei; see **Table 1** for a selection of elements. In practice, the signal is a mixture of coherent and incoherent scattering, unless the experiment is designed to select one type of scattering. The cross section is both element and isotope dependent. The most important feature is the enormous incoherent cross section of hydrogen; in contrast, deuterium and most other elements have a modest incoherent cross section and a significant coherent cross section. This means that the scattering from a protonic

Table 1 The coherent and incoherent scattering cross sections of selected elements

Element	Mass ^a (amu)	Scattering cross section (barns = 10^{-28}m^2)	
		Coherent	Incoherent
Hydrogen	1.0078	1.758	79.7
Deuterium	2.0141	5.597	2.04

Platinum	195.08	11.65	0.13

^aThe atomic mass given refers to the natural isotopic composition of the element except for hydrogen and deuterium where the mass is that of the isotopes ^1H and ^2H respectively.

sample will be mostly incoherent, while that from its deuterated isotopomer will be largely coherent. Isotopic substitution therefore provides a very powerful method to change the scattering characteristics of a sample.

The Energy Range ± 10 meV (± 80 cm⁻¹): Quasielastic Scattering and Tunnelling Spectroscopy

Quasielastic Scattering

Quasielastic scattering is concerned with scattered neutrons that have undergone small energy transfers, typically ≤ 2 meV (≤ 16 cm⁻¹). This originates from neutrons scattered by atoms that are undergoing diffusion or reorientation on a timescale of 10^{-12} – 10^{-7} s. Since the motions are not quantized, they form a continuous distribution, and the effect is manifested as a broadening of the peak due to the elastically scattered neutrons. This is entirely analogous to the Doppler broadening of an audio signal by reflection from a moving object. The neutron has a magnetic moment so it can be scattered magnetically and the random fluctuations of unpaired electron spins of stationary atoms can also cause quasielastic broadening.

In general, a molecule in a condensed phase will be simultaneously undergoing translation, rotation and vibration and the scattering law is a convolution of the scattering laws corresponding to the different types of motion. In practice, the vibrational term only affects the intensity as a Debye–Waller factor, $\exp(-Q^2 \langle u^2 \rangle)$, where $\langle u^2 \rangle$ is the mean square displacement in the vibrational modes. For hydrogenous materials the scattering will be incoherent and only the motion of the hydrogen atoms need be considered. In this case the scattering law can be written as the sum of an elastic and an inelastic component:

$$\begin{aligned} S(Q, \omega) &= \text{Elastic} + \text{Inelastic} \\ &= A_0(Q)\delta(\omega) + S^{\text{inc}}(Q, \omega) \end{aligned} \quad [1]$$

Provided that the experimental data can be resolved into elastic and inelastic contributions, the $A_0(Q)$ term can be determined from:

$$A_0(Q) = \frac{\text{Elastic intensity}}{\text{Total intensity}} \quad [2]$$

and is called the elastic incoherent structure factor (EISF). The elastic intensity can be considered to arise from motions that are localized in space and the inelastic arise from motions that are not localized. Thus for purely translational motion, the EISF is zero since there is no elastic peak. For rotational motion the EISF is unity at $Q = 0$ and falls to a minimum at a Q value that is related to the radius of gyration. At higher Q the EISF is oscillatory and the shape gives information on the geometry of the rotational process. This is most characteristic beyond the first minimum and

shows the importance of obtaining data at as wide a range of Q as possible.

Rotational motions in many different systems have been studied. In particular, methyl group rotations in polymers have been extensively studied. The rotational motion is represented by instantaneous jumps between three equivalent positions on a circle of radius R . When all orientations are equally likely, eqn [1] may be written as:

$$S(Q, \omega) = A_0(Q)\delta(\omega) + \frac{1}{\pi}[1 - A_0(Q)]L(\omega) \quad [3]$$

with the EISF given by:

$$A_0(Q) = \frac{1}{3}[1 + 2J_0(QR\sqrt{3})] \quad [4]$$

where $J_0(x)$ is the zeroth-order spherical Bessel function. $L(\omega)$ is a Lorentzian line shape:

$$L(\omega) = \frac{2\tau/3}{1 + \omega^2(2\tau/3)^2} = \frac{\Gamma}{\Gamma^2 + \omega^2} \quad [5]$$

whose full width at half maximum is given by 2Γ or $3/\tau$ (τ being the average time between jumps). **Figure 1a** shows the decomposition of the experimental data into an elastic and a quasielastic part for selectively deuterated poly (methyl methacrylate) at 25 °C. The deuterated part of the molecule gives considerable coherent scattering and after correction for this, the experimental data, **Figure 1b**, shows excellent agreement with the EISF calculated from eqn [4].

Recent work has shown that the data can be better modelled by a distribution of jump rates, since for amorphous polymers the methyl groups are in a variety of environments.

For translational diffusion, the simplest model is to consider that the diffusing particle starts at the origin at time zero. Since this is the dynamics of a single particle, the scattering is incoherent. In this case the scattering law takes the form:

$$S(Q, \omega) = \frac{1}{\pi} \frac{D_t Q^2}{(D_t Q^2)^2 + \omega^2} \quad [6]$$

where D_t is the tracer diffusion coefficient. This is valid at small Q (≤ 0.5 Å⁻¹) where the diffusion is being studied over long (tens of Å) distances, since in this case the details of the individual jumps (≤ 2 Å) are lost by averaging. The function is a Lorentzian with full width at half maximum of $D_t Q^2$, allowing D_t to be extracted from the width of the quasielastic peak at low Q .

For coherent scattering, there will only be intensity at low Q if the scattering atoms are in a compressible fluid. The intensity arises because at $t = 0$ there is an atom at the origin and hence excess concentration. This diffuses away in the same manner as for D_b , except that it is a concentration distribution that is studied. This gives rise

Figure 1 (a) Decomposition of the quasielastic scattering at $Q = 2.06 \text{ \AA}^{-1}$ from selectively deuterated syndiotactic poly(methyl methacrylate) at 25°C into a delta function (sharp component) superimposed on a Lorentzian (broad component), due to the ester methyl rotation. Both components are resolution broadened. (b) EISF for the same sample. The data points have been corrected for coherent scattering and the solid line is a fit using eqn [4]. (Data recorded with IN5 and IN6 beams at the Institute Laue Langevin (ILL).) to the chemical or Fick's law diffusion coefficient, D_{chem} , which is generally larger than D_t .

The diffusion of methane in the zeolite ZSM-5 can be treated using a more sophisticated version of the same idea that assumes that the jumps can be described by a Gaussian distribution of jump lengths. Physically, this corresponds to the molecule making jumps along the channel segments as well as across the channel intersections. Using this model, there is a more complex Q dependence, as shown in **Figure 2**. At small values of Q eqn [6] is obtained and at large values of Q the width tends asymptotically towards the mean jump rate. From the initial slope of the data in **Figure 2**, $D_t = 5 \times 10^5 \text{ cm}^2 \text{ s}^{-1}$ and the mean time between jumps is $3.6 \times 10^{-11} \text{ s}$.

A traditional strength, and still a major application, of INS is the study of hydrogen-in-metal systems. In these systems hydrogen occupies a well-defined lattice site, but is often free to move between sites. This proton mobility has led to numerous applications in battery technology, particularly for LaNi_5H_x and the AB_2 Laves phase compounds. The simplest model is to consider that: the jumps are all of the same length (l), that jumps in any direction are equally probable, and that the jump time is negligibly small compared to the residence time (τ). With these assumptions eqn [6] becomes:

$$S(Q, \omega) = \frac{1}{\pi} \frac{F(Q)}{[F(Q)]^2 + \omega^2} \quad [7]$$

Figure 2 The broadening of the elastic peak as a function of Q^2 for methane at a loading of 1.5 molecules per unit cell in ZSM-5 at 250 K. (Data recorded with IN5 at the ILL.) with

$$F(Q) = \frac{1}{\tau} \left(1 - \frac{\sin Ql}{Ql} \right) = \frac{6D_t}{l^2} \left(1 - \frac{\sin Ql}{Ql} \right) = \frac{6D_t}{l^2} (1 - \text{sinc } Ql) \quad [8]$$

Figure 3 (a) Scattering at $Q = 0.87 \text{ \AA}^{-1}$ and 360 K from $\text{ZrTi}_2\text{H}_{3.6}$. The fit (solid line) to the data ($\bullet$) is the sum of the quasielastic scattering with a Lorentzian line shape (dashed line) and elastic scattering from the metal atoms (dotted line). (b) Line width of the Lorentzian component as a function of Q for $T = 295$, 330 and 360 K. The solid lines are fits from the Chudley–Elliott model (eqn [8]) with $l = 2.8 \text{ \AA}$. (Data recorded with IN10 at the ILL.) Reproduced with permission from Fernandez JF, Kemali M, Johnson MR, and Ross DK (1997) Quasielastic neutron scattering measurements on the $\text{ZrTi}_2\text{H}_{3.6}$ C-15 Laves phase compound. *Physica B* 234–236: 903–905.

since $D_t = l^2/6\tau$. As shown in **Figure 3a** for $\text{ZrTi}_2\text{H}_{3.6}$, the scattering function is still Lorentzian but the line width has a more complex Q dependence **Figure 3b**. This model, known as the Chudley–Elliott model, was originally developed for the case of diffusion in liquids. It has since been extended to take account of sites that are different both crystallographically and energetically.

The neutron spin echo technique has been largely used to look at the main chain dynamics of polymers in concentrated solution or in the melt. In these systems the entanglements between chains determine key physical properties, particularly the viscosity, which is an area of central concern to the processing of polymers. The most successful theory to explain the properties of such systems is that of reptation. This considers the polymer to be confined to a ‘tube’ formed by its neighbours and that the only motion is a snake-like creep along the tube, lateral motion being prevented by the walls of the tube. However, there are competing theories and there was no

Figure 4 Plot of the normalized intermediate scattering function $[S(Q, t)/S(Q, 0)]$ versus time for hydrogenous polyethylene (12% w/w) in deuterated polyethylene at 509 K for $Q = 0.050$ and $0.077 \text{ \AA}^{-1}$. Also shown are the predictions from the reptation model (solid line) and competing models (dashed and dot-dashed lines). (Data recorded with IN15 at the ILL.) Reproduced with permission from Schleger P, Farago B, Lartigue C, Kollmar A, and Richter D (1998) Clear evidence for reptation in polyethylene from neutron spin echo spectroscopy. *Physical Review Letters* 81: 124–127.

direct experimental evidence that the reptation model is correct. For the case of hydrogenous polyethylene (12% w/w) in deuterated polyethylene, improvements in instrumentation have allowed the models to be tested. **Figure 4** compares the experimental data and the predictions of the various models. Clearly only the reptation model (solid line) accurately describes the data over the entire time range, thus providing compelling evidence that reptation is the best model.

Tunnelling Spectroscopy

Tunnelling is the movement of a particle from one site to another at temperatures where, classically, it does not have sufficient energy for the transition. Thus tunnelling is intrinsically a quantum phenomenon and is essentially restricted to motion of hydrogen (and its isotopes). It can be rotational or translational in origin. **Figure 5** illustrates a model for the hindered rotation in a system with three equivalent hydrogens such as $-\text{CH}_3$ or NH_3 . The crucial factors are the barrier height, V , and the rotational constant, B , of the molecule. As the ratio V/B decreases, the overlap of the ground-state wavefunctions increases. Since the energy levels of the protons in each well are

Figure 5 Model of the tunnel splitting (Δ) of the rotational ground state and of the first excited torsional state. The splitting is due to the overlap of the wavefunctions (hatched region) in neighbouring wells.

the same, they are degenerate and they split to remove the degeneracy. The degree of splitting is the tunnelling splitting. Since the wavefunctions are approximately Gaussian, the splitting depends exponentially on the barrier height, making the tunnel splitting a very sensitive probe of the immediate environment of the molecule. INS is sensitive to tunnel splittings in the range $0.1 \mu\text{eV}$ (10^{-4} cm^{-1}) to 5 meV (40 cm^{-1}).

Intercalation of graphite with small molecules is used to modify its physical and chemical (including catalytic) properties. **Figure 6a** shows the rotational tunnelling of ammonia in a caesium–graphite intercalate $\text{C}_{28}\text{Cs}(\text{NH}_3)_x$. As x varies from 0.0 to 1.90 the tunnelling peaks can be seen to grow and decay as the layers of caesium atoms in the layers become coordinatively saturated by ammonia ligands. The peaks occur in pairs at $\pm$ energies because even at the low temperature of the experiment, the first excited state is populated, thus both neutron energy gain and neutron energy loss peaks are observed. The staging behaviour is reproduced in the diffraction pattern of the intercalate which was recorded simultaneously (**Figure 6b**). The ability to obtain structural and dynamic information simultaneously is a unique aspect of neutron studies. Tunnelling is very strongly temperature dependent and is only usually observed at very low temperatures. As the temperature is raised the intensity and transition energy of the lines decrease, while simultaneously a broad quasielastic feature appears.

One of the major discoveries in chemistry in recent years is the characterization of a series of complexes where dihydrogen, H_2 , acts as a ligand. For the compounds $\text{M}(\text{CO})_3(\eta^2\text{-H}_2)(\text{PR}_3)$ ($\text{M} = \text{Mo}$, $\text{R} = \text{cyclohexyl}$; $\text{M} = \text{W}$, $\text{R} = \text{cyclohexyl}$, isopropyl) the tunnel spectra are shown in **Figure 7**. The observation of the tunnel splitting is proof that the H–H bond is intact. It can be seen that changing the metal has a large (300%) effect on the tunnel splitting (compare **Figure 7a** and **Figure 7b** and **7c**), whereas changing the phosphine has a minor (20%) effect (compare **Figure 7b** and **Figure 7c**), indicating that the electronic component of the M– H_2 bonding is more significant than the steric influences of the phosphines. (Two peaks in the gain and loss spectra are observed because of crystallographic disorder.)

Translational tunnelling is conceptually different since the hydrogen may be in a different crystallographic site after the tunnelling event. Hydrogen-in-metal systems

Figure 6 Neutron studies of $\text{C}_{28}\text{Cs}(\text{NH}_3)_x$ (from top to bottom $x = 1.90, 1.54, 1.25, 0.94, 0.74, 0.42, 0.20, 0.0$). may show this type of tunnelling. **Figure 8** shows the tunnelling transition of hydrogen in $\alpha\text{-Mn}$. The tunnelling in this instance is between two sites of the same symmetry separated by 0.68 Å . This is a very unusual system in that the tunnelling energy is 6.3 meV (51 cm^{-1}), which is ~ 15 times higher than commonly found for hydrogen-in-metal systems, and the integrated intensity is very large when compared to the optic modes at $80\text{--}120 \text{ meV}$ ($645\text{--}968 \text{ cm}^{-1}$).

The Energy Range 0–1 eV (0–8000 cm⁻¹): Vibrational Spectroscopy and Magnetic Excitations

Coherent INS Spectroscopy

Coherent INS spectroscopy gives information on collective motions in crystals. These are important in understanding phenomena as diverse as magnetism, phase transitions and thermodynamic properties. Neutron diffraction is coherent

Figure 8 Hydrogen tunnelling in α -Mn. The intensity of the tunnelling line at 6.3 meV (51 cm⁻¹) is unusually large when compared to the optic modes at 80–120 meV (645–968 cm⁻¹). (Data recorded with TFXA at ISIS.)

elastic scattering from a notionally static lattice; coherent one-phonon neutron scattering can be considered to be ‘diffraction’ from a lattice where the atoms are undergoing sinusoidal motion of frequency given by the phonon frequency. This means that the scattering occurs in specific directions at specific energies. It is to be emphasized that coherent INS is the most general method of measuring the excitations (which can be vibrational or magnetic in origin) across the entire Brillouin zone.

Palladium hydride has been extensively studied because of its ready take-up and large capacity for hydrogen. This has led to interest in its use as a hydrogen storage material. **Figure 9a** shows one of the measured transitions for PdD_{0.63} and **Figure 9b** shows the dispersion curves derived from the data. The lower set of curves are the acoustic modes, where all the atoms in the unit cell move in the same direction (as is the case for sound waves) and largely reflect the dynamics of the metal atoms. The higher energy curves are the optic modes and different types of atom move in different directions. This generates a changing dipole, and these modes would give rise to infrared or Raman active modes. Infrared and Raman spectroscopies only observe modes at approximately zero wave vector and from **Figure 9b** only the optic modes have nonzero frequencies at $Q = 0$.

Figure 9 (a) Example of a phonon group in PdD_{0.63} and (b) the dispersion curves for PdD_{0.63}. The dashed lines are the dispersion curves for pure Pd (r.l.u. = reciprocal lattice unit) (data recorded with HB3 at Oak Ridge). Reproduced with permission from Rowe JM, Rush JJ, Smith HG, Mostoller M, and Flotow HE (1974) Lattice dynamics of a single crystal of PdD_{0.63}. *Physical Review Letters* 21: 1297–1300.

It is one of the great strengths of INS that modes at all wave vectors can be studied.

The comparatively low energy of the optic modes indicates that the Pd–D force constant is small. For PdD_{0.63} the variation of energy transfer with wave vector (dispersion) of the optic modes shows that there are strong interactions between the H atoms. To fit the data fourth-nearest neighbours have to be included. Comparison of the acoustic modes for PdD_{0.63} and Pd (dashed lines) shows that the former are lower in energy so the bonding is weaker. This is consistent with the lattice expansion observed on hydrogen (deuterium) take-up.

The unique properties of water are essential to life but are still not understood in detail. They derive from the hydrogen bonding present in water which is manifested in the complex phase diagram and anomalously high melting point of ice. Coherent INS studies of ice *I_b* provide a stringent test of models of the dynamics. **Figure 10a** shows one of the measured spectra for a single crystal of D₂O ice *I_b* and **Figure 10b** shows the derived dispersion curves. It can be seen that while the longitudinal acoustic (LA) and transverse acoustic (TA) modes, which mainly involve oxygen motion, are sharp, the transverse optic (TO) mode is broad. The TO mode is largely due to deuteron motion and the width probably

reflects the highly disordered arrangement of deuterons (protons) in ice *I_b*.

Virtually all of our understanding of magnetism at the atomic level is based on neutron scattering; neutron diffraction allows the orientation of the spins in the lattice to be determined and inelastic scattering allows their dynamics to be studied.

Magnetoresistance is a phenomenon observed in some materials where the electrical resistivity changes in an applied magnetic field. There has been a huge revival in the study of manganese perovskites which, depending on the addition of other elements, can change their resistance by several orders of magnitude in fields of a few tesla; this is known as colossal magnetoresistance (CMR). The interest in these materials is not just because of possible technological applications, particularly read-out heads for hard disks that will allow much higher storage densities and faster access, but also because of fundamental questions relating to the transition between metallic and insulating phases.

The CMR manganites are metallic and derived from the insulating ionic compound LaMnO₃. Partial substitution of La³⁺ by a divalent metal ion e.g. Ba²⁺, Sr²⁺, Pb²⁺, introduces mobile charge carriers and these are responsible for the unusual behaviour. The materials are

Figure 10 (a) One of the measured spectra of the phonon dispersion along the (10,0) direction about the (11,0) reciprocal lattice point of D_2O ice I_h . (b) The derived dispersion curves; the solid lines are fits to the TA and LA modes. The dashed lines show the Q, ω trajectories available in this experiment (r.l.u. = reciprocal lattice unit) (data recorded with PRISMA at ISIS).

ferromagnets in which the magnetic moments associated with the manganese ions are aligned in the same direction below the Curie temperature. In 1930 Bloch showed that the lowest energy excitations in a ferromagnet are spin waves; coherent precessions of the spins around their average orientation. **Figure 11** shows an image of the inelastic magnetic scattering by a single crystal of $La_{0.7}Pb_{0.3}MnO_3$. The spin wave is clearly seen as a ring of scattering around the (1, 0, 0) reciprocal lattice point. From the spectra the dispersion relation for the spin wave can be obtained by plotting the position of maximum intensity along the main directions of crystal symmetry. Fitting the data shows that the dynamics can be described by only considering nearest neighbours, a surprising result for such a complex material.

Incoherent INS Spectroscopy

Incoherent INS spectroscopy probes the local environment of the scattering atom and is thus complementary to

infrared and Raman spectroscopies. However there are important differences as illustrated in **Figure 12a–c** which shows the infrared, Raman and INS spectra respectively, of *N*-phenylmaleimide, a model compound for bismaleimide composites that are used in aerospace applications. It can be seen that all three spectra are very different. There are two main reasons for this. Firstly, whether a mode is infrared and/or Raman active (or is inactive in both) is determined by the symmetry of the molecule. Note that even when a mode is allowed it may still have little or no intensity. In contrast, there are no selection rules for INS spectroscopy and all modes are allowed.

The strongest bands in the infrared and Raman spectra are the out-of-phase carbonyl stretch at 212 meV (1707 cm^{-1}) and the in-phase carbonyl stretch at 219 meV (1770 cm^{-1}) respectively. In contrast, the carbonyl bands are completely absent in the INS spectrum, but there are several strong bands that do not have any obvious counterparts in the infrared and Raman spectra.

The differences arise because the intensity of the i th INS band at a frequency ω_i is proportional to:

$$S(Q, \omega_i) \propto \sum_d \frac{|Q U_d^i|^2}{m_d \omega_i} \sigma_d^{\text{inc}} \exp(-Q^2 U_{\text{total}}^2) \quad [9]$$

The exponential term is the Debye–Waller factor, U_{total}^2 is the mean square displacement of the molecule and its magnitude is in part determined by the thermal motion of the molecule. This can be reduced by cooling the sample and so spectra are typically recorded below 30 K.

U_d^i is the amplitude of vibration of the d th atom in the i th mode, σ_d^{inc} and m_d are its incoherent cross section and mass respectively. From **Table 1** it can be seen that if hydrogen is present, the combination of large incoherent cross section and small mass means that the scattering from hydrogen will dominate the spectrum. For hydrogenous materials the scattering from all other atoms can be neglected. This dependence on the cross section is why the INS spectrum is so different from the optical spectroscopies. There, the intensity derives from changes in the electronic properties of the molecule that occur as the vibration is executed (the dipole moment and the polarizability for infrared and Raman spectroscopy respectively).

The cross-section dependence can be exploited to ‘eliminate’ parts of the molecule from the spectrum. **Figure 12d** is again *N*-phenylmaleimide but with the phenyl ring deuterated. This results in a considerable simplification of the spectrum and all of the modes can be assigned to vibrations of the maleimide ring with the phenyl group treated as a point mass.

Vibrational spectroscopy is a commonly used tool for the study of catalysts. The neutron is a particle with zero charge which means that it is highly penetrating and is

Figure 11 (Left) Image of the magnetic excitations in $\text{La}_{0.7}\text{Pb}_{0.3}\text{MnO}_3$. (Right) Data plotted in a three-dimensional space defined by two coordinates of momentum in the horizontal plane and the energy vertically. The shaded surface indicates the possible energies and momenta of the scattered neutrons that are accessible in this experiment; maximum intensity occurs where this surface intersects the dispersion surface of the spin waves (r.l.u. = reciprocal lattice unit) (data recorded with HET at ISIS).

Figure 12 Vibrational spectra of *N*-phenylmaleimide: (a) infrared, (b) Raman, (c) INS, (d) INS spectrum of *N*-(perdeuteriophenyl)maleimide (INS data recorded with TFXA at ISIS).

not a surface-sensitive probe. This can be circumvented by using high surface area materials and hydrogenous adsorbates that offer contrast to the substrate. The advantages are that common catalyst-supports such as silica, alumina and carbon are weak scatterers, see **Table 1**, and the entire 0–500 meV (0–4000 cm^{-1}) ‘mid-infrared’ range is accessible, and in particular the low-energy range below 125 meV (1000 cm^{-1}). This range is very difficult to study with optical methods; the supports tend

to be highly absorbing and the important metal–adsorbate vibrations are often very weak.

Formate (HCOO) species adsorbed on a copper-based catalyst are a key intermediate in the industrial synthesis of methanol from CO_2 and H_2 . INS spectra were recorded for a number of different copper surfaces; spectra were taken before and after formic acid adsorption. In all the spectra adsorbed, formate could be clearly distinguished even though it represented less than 1% of the total mass in the beam. The difference spectrum ($[\text{CuO} + \text{formate}] - [\text{CuO}]$) is shown in **Figure 13a**.

Equation [9] is noteworthy in that the intensity of a mode is determined only by the cross section, the momentum transfer and the amplitude of vibration, hence it is purely dynamic. From a conventional Wilson–Decius–Cross normal coordinate analysis it is possible to calculate both the energies (from the eigenvalues) and intensities (from the eigenvectors) for INS spectra of molecular species. The requirement to fit the INS intensities is a stringent test of any force field. The spectrum calculated for a bidentate configuration of formate bound to two Cu atoms (**Figure 13b**) gives good agreement with the experimental data, supporting this as the mode of binding on this surface. It also demonstrated that the mode at 26.8 meV (216 cm^{-1}) is the Cu–O torsion, which was the first time this mode was detected on a surface.

The rapid growth in computer power means that increasingly complex systems can be treated by *ab initio* quantum chemistry techniques. The vibrational spectrum of the object of interest is often calculated, since this offers

Figure 13 Experimental (a) and calculated (b) spectra of bridging formate on CuO. The experimental spectrum is the difference spectrum [CuO + formate] – [CuO]. (Data recorded with TFXA at ISIS.)

a check of whether the structure is a true minimum or a saddle point on the potential surface, as well as being a rigorous test of the results. The amplitudes of vibration are calculated as part of this process and it is relatively straightforward to derive the INS spectrum from these via eqn [9]. In contrast, the infrared and Raman intensities are poorly reproduced for anything but the simplest systems. The use of *ab initio* methods is undoubtedly the way that INS data will be routinely analysed in the near future. The power of the method is illustrated in **Figure 14** where it allows an unambiguous differentiation between two possible modes of water binding to the Brönsted acid sites of a zeolite. Clearly, the hydrogen-bonded water model fits the data better than the hydroxonium ion, H_3O^+ , model.

The Energy Range $> 1 \text{ eV}$ ($> 8000 \text{ cm}^{-1}$): Neutron Compton Scattering

Neutron Compton scattering (NCS) is the measurement of atomic momentum distributions, $n(\mathbf{p})$, in condensed matter systems by high-energy inelastic neutron scattering. NCS measurements are particularly important in the study of quantum fluids.

For protons, $n(\mathbf{p})$ is related to the Fourier transform of the proton wavefunction and an NCS measurement of $n(\mathbf{p})$ can be used to determine the wavefunction in a way analogous to the determination of a real space structure from a diffraction pattern. If $n(\mathbf{p})$ is known then, in principle, both the proton wavefunction and the exact form of the potential energy well can be reconstructed.

For accurate NCS measurements energy transfers much greater than the maximum vibrational frequency are required for the impulse approximation to be valid. In the impulse approximation, momentum and energy are

Figure 14 INS spectrum of water adsorbed at low loading on H-ZSM5. (a) Experimental spectrum. *Ab initio* simulation for: (b) water hydrogen-bonded to a bridging hydroxyl and (c) a hydroxonium ion, H_3O^+ . (Data recorded with IN1BeF at ILL.) conserved in the scattering event and from a measurement of the momentum and energy change of the neutron, the momentum of the proton before the collision can be determined. This requires neutrons with energies $> 1 \text{ eV}$ and only spallation sources provide a sufficient flux of high-energy neutrons for the measurement to be feasible. At lower energies the impulse approximation is no longer valid and $n(\mathbf{p})$ is not related in a simple way to the observed intensities.

Figure 15 Time-of-flight spectra for α -LaNi₅: (a) nominally hydrogen-free (however, note the small peak at 275 μ s due to hydrogen), (b) after absorption of hydrogen. (Data recorded with eVS at ISIS.) Reproduced with permission from Gray EMA, Kemali M, Mayers J, and Norland J (1997) Interstitial site occupation in α -LaNi₅ studied by deep inelastic neutron scattering. *Journal of Alloys and Compounds* 253–254: 291–294.

An important feature is that the neutron energy loss depends on the atomic mass of the scattering atom and hence different masses occur at different times-of-flight. In the harmonic approximation, the peak width depends on the Gaussian average of the vibrational frequencies. The peak intensity depends only on the number of

scatterers and their cross section. Thus NCS functions as a ‘neutron mass spectrometer’, albeit with poor mass resolution. Hydrogen is usually well separated from other elements and allows its quantification, even in the presence of deuterium.

This aspect of NCS has been exploited in the study of the battery material LaNi₅. For a well-annealed polycrystalline sample of α -LaNi₅ after hydrogen desorption, there should be no residual hydrogen. **Figure 15a** shows an intense peak at 375 μ s due to the metal atoms and a weak feature at 275 μ s assigned to hydrogen. This is confirmed by the absorption of hydrogen, resulting in an increase of the scattering at 275 μ s (**Figure 15b**). Analysis shows that the nominally hydrogen-free material has a hydrogen-to-metal ratio of 0.017 ± 0.002 , indicating that there is a significant number of trap sites, which are probably detrimental to battery performance.

Introduction

The prime requirement for inelastic neutron scattering (INS) spectroscopy is a source of neutrons. The only methods that produce a sufficient flux of neutrons ($>10^{14}$ neutrons $\text{cm}^{-2} \text{s}^{-1}$) for spectroscopy are: ^{235}U fission in a nuclear reactor and spallation. The latter process involves accelerating a beam of protons to near-light-speed and impacting them onto a heavy-metal target, usually made of either depleted uranium or tantalum. The target atoms absorb the protons, generating highly excited nuclei that decay, in part, by emission of neutrons. In the case of a uranium target, fission also occurs, increasing the neutron yield. Typically, a reactor yields one neutron per fission event that is available for spectroscopy, while spallation yields up to 30 neutrons per proton absorbed. At present there are neutron source facilities in many countries including, Australia – ANSTO-HIFAR Reactor (Sydney); Canada – Chalk River Laboratories Canadian Neutron Facility; Great Britain – ISIS Spallation Source, Rutherford – Appleton Laboratory (Oxford); France: – ILL: – Institut Laue Langevin LLB, Léon Brillouin Laboratory at CEA

(Saclay); Germany – FRM II Technical University (Garching), FRJ-2 (Bonn), GKSS – Institute for Materials Research (Hamburg), Hahn-Meitner Institute (Berlin); Hungary – KFKI Research Institute (Budapest); India – Dhruva, CIRUS and Apsara: Bhabha Atomic Research Centre, Mumbai; Japan – Atomic Energy Research Institute, KENS – High Energy Accelerator Organisation, KEK KURRI – Research Reactor Institute (Kyoto), JSNS – part of the Japan proton accelerator research complex; Netherlands – Interfaculty Reactor Institute, Delft University of Technology; Russia – IBR Fast Pulsed Reactors (Dubna), Jointed Institute for Nuclear Research (Dubna); Sweden – NFL Studsvik Neutron Research Laboratory (Studsvik); Switzerland – Paul Scherrer Institute; USA – High Flux Beam Reactor (Brookhaven), Los Alamos Neutron Science Center (Los Alamos), NIST – Center for Neutron Research (Washington), ORNL – High Flux Isotope Reactor (Oak Ridge), SNS – Spallation Source, Oak Ridge (Tennessee).

By whatever process they are produced, the ‘new-born’ neutrons are very energetic, $>2 \times 10^9$ meV ($1 \text{ meV} = 8.067 \text{ cm}^{-1} = 0.241 \text{ THz}$) and must be brought to useful energies by multiple inelastic collisions in a moderator; this is usually a hydrogenous material. By suitable design it is possible to establish a quasi-thermal equilibrium between the temperature of the moderator and the energy of the neutrons, which provides a means of tailoring the neutrons’ energy to the requirements of the experiment.

Neutrons are quantum entities, so they exhibit both particle-like and wave-like properties. For INS spectroscopy, the particle-like properties are relevant since the neutron–sample interaction occurs on a femtosecond timescale and the interaction can be considered to be analogous to billiard-ball scattering. However, the selection of the incident energy or the analysis of the scattered neutrons’ energy often uses Bragg diffraction from a single crystal, making use of the wave-like properties. **Table 1** shows the relationships between the units commonly used.

INS spectroscopy spans an enormous energy range, which is equivalent to a wide range of timescales. **Figure 1** illustrates the ranges available and some of the applications. It is convenient to divide the whole energy range into three sectors, while recognizing that there is

Table 1 Relationship between neutron properties and typical values

Neutron energy				Wavelength (Å)	Wave vector (Å ⁻¹)
meV	cm ⁻¹	THz	K		
E			$= k_B T$	$= \frac{h^2}{2m\lambda^2}$	$= \frac{h^2 k^2}{2m}$
E	$= 8.0667 E$	$= \frac{E}{4.1354}$	$= 0.086165 T$	$= \frac{81.787}{\lambda^2}$	$= 2.0717 k^2$
0.01	0.081	0.00242	0.116	90.4	0.0695

10 000.0	80 667	2 418	116 056	0.090	69.48

meV = millielectronvolt, cm⁻¹ = wavenumber, THz = terahertz (10¹² Hz), K = kelvin, Å = angstrom (10⁻¹⁰ m), h = Planck's constant, $\hbar = h/2\pi$, m = neutron mass, k_B = Boltzmann's constant.

Figure 1 Illustration of the energy range and the equivalent timescales and length scales available with inelastic neutron scattering. The type of information available is also indicated.

significant overlap between them. In the lowest energy range, ± 10 meV, the applications are principally quasielastic scattering and tunnelling spectroscopy. The second range, 0–1000 meV, covers the regions of vibrational spectroscopy and magnetic excitations. The highest range above 1000 meV is the province of neutron Compton scattering.

The major difference between INS spectroscopy and the photon-based spectroscopies that cover the same energy range is that the neutron has a significant mass (1.009 amu). Thus an inelastic collision results in transfer of both momentum (Q , Å⁻¹) and energy (E , meV). In contrast, optical processes result in essentially zero

momentum transfer. The aim of an INS experiment is, usually, to measure scattered intensity at each energy transfer as a function of the momentum transfer. In **Figure 2** the scattering process is shown in both real space and reciprocal space.

The energy transfer, $\hbar\omega$, is given by the difference in the incident (i) and final (f) neutron energies:

$$\hbar\omega = E_i - E_f \quad [1]$$

where E is the kinetic energy of the neutron and

$$E = mv^2/2 \quad [2]$$

Figure 2 Neutron scattering in (a) real space and (b) reciprocal space.

Figure 3 The Q , E coverages of some of the instruments at (a) the ILL and (b) ISIS.

where m is the neutron mass and v its velocity. The momentum transfer, Q , is given by:

$$Q = \sqrt{(k_i^2 + k_f^2 - 2k_i k_f \cos \theta)} \quad [3]$$

where θ is the scattering angle and k ($\text{\AA}^{-1}$) is the wave-vector:

$$k = 2\pi/\lambda \quad [4]$$

associated with the wavelength, λ ($\text{\AA}$). Thus INS offers the possibility of exploring both momentum and energy transfer and can be considered to be a 'two-dimensional' form of spectroscopy. This is illustrated in **Figure 3** which shows the Q , E coverages of some of the instruments at ISIS and the ILL.

The Energy Range ± 10 meV: Quasielastic Scattering and Tunnelling Spectroscopy

Quasielastic scattering is a very low energy inelastic process. The term is usually taken to mean a broadening of the elastic line and is most commonly the result of diffusional (translational or rotational) motion of atoms. (It can also be caused by the random fluctuations of unpaired electronic spins of stationary atoms.) Translational and rotational diffusion occur simultaneously but on

different time-scales. The energy resolution of a spectrometer, ΔE , and the timescale τ of the motion are related by the Heisenberg uncertainty principle:

$$\Delta E \times \tau \sim h/2\pi \quad [5]$$

Thus rapid motions require relaxed resolution, while slower motions require high resolution. Note that these are relative terms; typically an energy resolution of better than 1% $\Delta E/E$ and 100 μeV is required. The timescale to be probed can be separated into three regimes, each of which uses a different technique: for $\tau \sim 10^{-11}$ s, ΔE is 10–100 μeV and direct-geometry time-of-flight is used, for $\tau \sim 10^{-9}$ s, ΔE is 0.3–20 meV and a backscattering crystal analyser is used, for $\tau \sim 10^{-7}$ s, ΔE is 0.005–1 μeV and neutron spin echo is used. Examples of each type of spectrometer will be considered.

Direct-Geometry Time-of-Flight

For time-of-flight INS spectroscopy it is necessary to determine either the incident energy or the final energy of the neutron. Spectrometers that define the neutron's final energy are indirect-geometry instruments and those that determine the neutron's incident energy are direct-geometry instruments. In a direct-geometry quasielastic spectrometer, a monochromatic (single energy), pulsed beam of neutrons is produced by a rotating mechanical

Figure 4 Layout of the cold-neutron multi-chopper spectrometer IN5 at the ILL. chopper system. This pulse of neutrons is incident upon the sample and, after interacting with the atoms of the sample, the scattered neutrons are timed over a known distance to the detectors which are set at a range of scattering angles. The time-of-flight, T_1 , from the sample to the detectors is given by $T_1 = L_1/v_1$, where L_1 is the sample-to-detector distance. Since the incident neutron velocity, v_0 , is known it follows from eqns [1] and [2] that the energy transfer, $\hbar\omega$, is:

$$\hbar\omega = \frac{m}{2}(v_1^2 - v^2) = \frac{mL_1^2}{2}\left(\frac{1}{T_1^2} - \frac{1}{T^2}\right) \quad [6]$$

where T_0 is the time-of-flight of the elastically scattered neutrons. Using eqn [3] and the known angular position of the detectors the momentum transfer Q of the detected neutrons can also be determined.

Figure 4 illustrates the principle for the multi-chopper time-of-flight spectrometer IN5 at the ILL. The incoming neutron distribution spreads from ~ 36 meV ($1.5 \text{ \AA}$) to ~ 0.25 meV ($18 \text{ \AA}$) with a maximum flux at 3.3 meV ($5 \text{ \AA}$). As chopper 1 opens, a pulse of neutrons is admitted; the only neutrons that pass through the last chopper (number 4) are those with the correct velocity to arrive at chopper 4 as it opens. Thus the energy of the neutrons incident on the sample is determined by the phase angle between the first and the last choppers. Neutrons with velocities that are one-half of the desired value would also pass through chopper 4 after a further revolution; these are eliminated by chopper 2. Chopper 3 spins at an integral fraction of the speed of the other choppers and eliminates a certain number of pulses, for example 1 in 2, or 3 in 4. This is to prevent frame-overlap, where fast neutrons from a following pulse

overtake slow neutrons from the previous pulse. This is a problem since the time-of-flight method depends on knowing when a given neutron was created; from eqn [6] any uncertainty in the time-of-flight translates into a corresponding uncertainty in the energy transfer.

Backscattering Crystal Analyser

The backscattering crystal analyser is an example of an indirect-geometry spectrometer and is used when higher resolution is required. Neutrons with a band of energies whose width (in energy) is greater than the maximum energy transfer to be measured are incident on the sample. From the scattered neutrons, one neutron energy is selected by Bragg diffraction from a single crystal. Bragg's law states:

$$\lambda = 2d \sin \theta \quad [7]$$

where λ is the incident neutron wavelength, d is the interplanar spacing in the analyser crystal and θ is the angle of incidence. The resolution is determined by the differential:

$$\frac{\Delta E}{E} = 2 \frac{\Delta \lambda}{\lambda} = 2 \left([\Delta \theta \cot \theta]^2 + \left[\frac{\Delta d}{d} \right]^2 \right)^{0.5} \quad [8]$$

The dominant term in most cases is $\cot \theta$ since for most single crystals the uncertainty in the lattice parameter is $\sim 10^{-4}$ and can be ignored. In the limit as the Bragg angle approaches 90° , $\cot \theta$ tends to zero and the energy resolution of the analyser becomes extremely good, being $0.5 \mu\text{eV}$ for silicon and $10 \mu\text{eV}$ for graphite. Hence, the term 'backscattering spectrometer'.

Figure 5 Schematic view of the cold-neutron spectrometer IN10 at the ILL. The incident energy is changed either by Doppler-shifting the neutron wavelengths (IN10A) or by thermal expansion of the monochromator (IN10B). Reproduced with permission of Adenine Press from Ferrand M (1997) Neutron instrumentation in studying dynamics of biomolecules. Figure 6 Schematic of the cold-neutron backscattering spectrometer IRIS at ISIS. Reprinted from *Physica*, 182B, Carlile CJ and Adams MA, 431–440, 1992, with kind permission of Elsevier Science – NL, Sara Burgerhartstraat 25, 1055 KV Amsterdam, The Netherlands.

The implementation of a backscattering spectrometer is somewhat different at a reactor than at a spallation source. **Figure 5** shows a schematic view of the spectrometer IN10 at the ILL and **Figure 6** shows the equivalent spectrometer IRIS at ISIS.

IN10 sits at the end of a cold-neutron guide. For low-energy (long-wavelength) neutrons, total external reflection occurs with a corresponding increase in transmission as compared to a tube of the same diameter. This provides a means of transporting neutrons long

distances, several tens of metres, without the intensity decrease that would result from solid-angle considerations. High-energy neutrons do not undergo total reflection and pass through the walls of the guide. By making the guide gently curved, with a radius of curvature of the order of a kilometre, a guide can also provide a means of selecting the neutrons of interest.

On IN10 the energy scan is performed by varying the energy of the incident neutrons. One may do this scan, which typically covers $\pm 15 \mu\text{eV}$ for 2 meV incident neutrons, by oscillating the monochromator to produce a Doppler shift in the velocity of the neutrons impinging on the sample. An alternative scanning procedure is to slowly vary the temperature and hence the lattice constant of the monochromator.

It can be seen in **Figure 6** that the analyser system on IRIS is similar to that of IN10 but that the incident white beam is generated differently. From the neutron pulse emitted by the liquid-hydrogen moderator, a broad band of neutron energies is selected by a rotating disc chopper at 6.4 m. The required energy resolution in the incident beam is achieved by allowing this band of neutrons to disperse in time over a long distance as it drifts along a curved neutron guide to the sample situated at 36 m from the moderator. Neutrons whose energies change to precisely match the analyser energy after scattering from the sample are selected by Bragg scattering from the pyrolytic graphite crystal array in near-backscattering geometry. A continuous range of scattering angles from 15° to 165° is covered simultaneously by the analyser-detector array. Using the 002 reflection from the graphite analyser an elastic resolution of $15 \mu\text{eV}$ is provided over an energy transfer range from $+4 \text{ meV}$ to -1 meV .

An advantage of all indirect-geometry instruments at spallation sources is that a relatively broad range of neutron wavelengths is incident on the sample. This

means that it is possible to add a diffraction capability simply by the addition of detectors that have a clear view of the sample; see **Figure 6**. This allows information on both structure and dynamics to be collected simultaneously. Inelastic scattering is much weaker than elastic scattering, so over the timescale of the experiment a few diffraction detectors will be sufficient to record a diffraction pattern of good quality.

Neutron Spin Echo

The highest energy resolution is obtained by using the neutron spin echo technique. In this type of instrument, the velocities of neutrons incident on, and scattered from, a sample are coded as the number of Larmor precessions that the neutron spins undergo in a well-defined applied magnetic field. The method requires a beam of polarized neutrons with a distribution of velocities. As indicated in **Figure 7**, these neutrons enter the precession-field region with their spins perpendicular to the field. As a neutron traverses this field, it precesses and the number of precessions is directly proportional to the time it spends in the magnetic field and thus inversely proportional to its velocity. After scattering by the sample, the spins 'unwind' in a reverse-precession-field region. The method is unique in using the magnetic moment of the neutron to detect the velocity change rather than the wave (as in the backscattering spectrometer) or particle properties (as in the direct-geometry spectrometer).

If the scattering at the sample is elastic and the precession fields before and after the sample are identical in magnitude and spatial extent, all neutrons will be in phase at the point in space where they leave the second precession region. This alignment of spins is the 'echo'. However, if the scattering is not purely elastic, the spins will not be completely in phase, weakening the echo. The

Figure 7 Schematic diagram of a neutron spin echo spectrometer. The direction of the neutron spin is shown as it traverses the spectrometer. Reproduced with permission of Adenine Press from Ferrand M (1997) Neutron instrumentation in studying dynamics of biomolecules. In: Cusack S, Büttner H, Ferrand M, Langan P, and Timmins P (eds.) *Biological Macromolecular Dynamics*. Schenectady: Adenine Press.

distribution of phases is then a measure of the distribution of the atomic velocities in the sample.

The high resolution of this technique stems from the large number of precessions the neutron undergoes, $\sim 10^5$ precessions m^{-1} . As a result, the velocity can be measured to an accuracy of better than 10^{-5} and hence the energy exchange can be measured to similar accuracy.

Another feature that is unique to neutron spin echo is that the signal, which is the neutron polarization at the echo point, is directly proportional to the intermediate scattering function, $I(Q, t)$, which is the Fourier transform of the scattering function $S(Q, \omega)$. This is in contrast to the other types of spectrometer that measure $S(Q, \omega)$. It is often advantageous to calculate $I(Q, t)$ rather than $S(Q, \omega)$.

The Energy Range 0–1000 meV: Vibrational Spectroscopy and Magnetic Excitations

This energy range corresponds to the mid- and near-infrared regions of the electromagnetic spectrum. This is the province of vibrational spectroscopy where the forces between atoms in condensed matter can be investigated directly. It is also the region where magnetic excitations are observed. These are electronic transitions between the energy levels of a metal atom (or ion) and usually involve d or f orbitals. They are often optically forbidden and the transitions can be observed by INS because of their interaction with the magnetic moment of the neutron.

Neutrons in this energy range are known as thermal neutrons, because typical energies correspond to room temperature; see **Table 1**. Thermal-neutron INS spectroscopy was the first type to be studied and the instrument invented by Bertram Brockhouse in 1952, the triple-axis spectrometer, is still a mainstay of inelastic instrumentation at reactor sources. In 1994, Brockhouse, together with the pioneer of elastic neutron scattering (diffraction) Clifford Shull, received the Nobel prize for physics for his invention and subsequent work with it.

The triple-axis spectrometer is designed to study coherent excitations, which give information about the relative motions of the nuclei. This approach mandates the use of single crystals and these need to be very large, of the order of several cubic centimetres. The scattering from powders and liquids is largely incoherent, which gives information about the motions of the individual nuclei. For these types of materials different spectrometers are used. Spectrometers for coherent and incoherent INS spectroscopy will be considered separately, although this division is one of convenience only.

Spectrometers for Coherent INS Spectroscopy

The principle of the triple-axis spectrometer is displayed in **Figure 8**. The prerequisite is a neutron source with a

Figure 8 General layout of the hot-neutron triple-axis spectrometer IN1 at the ILL.

constant flux, which can be a steady reactor or a continuous spallation source. A monochromatic neutron beam is selected from the neutron source by using Bragg reflection from a single crystal, the monochromator. This beam is then incident on the sample. In a selected direction another single crystal, the analyser, is positioned in such a way that only a given wavelength can be reflected; a neutron detector is placed after this analyser. If neutrons are counted in the detector, this means that there has been some process in the sample which has induced the specific changes of trajectory and wavelength of the incident neutrons.

The important point is that a given configuration of the spectrometer corresponds to a single point in (Q, ω) space. Changing step-by-step either k_i or k_f , the crystal is rotated and the scattering angle varied so as to scan the (Q, ω) space and detect all possible neutron-scattering processes, which can be vibrational (phonons) or magnetic (magnons) in origin. Furthermore, a given (Q, ω) point may be obtained in different ways (varying, for instance, either k_i or k_f). This gives the experimentalist the possibility to adjust conditions to the specific requirements of a given problem.

The great strength of triple-axis spectroscopy is simultaneously its Achilles heel. The instrumentation is enormously flexible and, in principle, any point in (Q, ω) space is accessible. However, it is a point-by-point method and this means that it is slow and to map the phonon dispersion in one sample can require weeks of measurement time.

The pulsed-source equivalent of a triple-axis spectrometer is demonstrated by PRISMA at ISIS. The difference is that a white beam of neutrons is incident on the sample, rather than a monochromated beam. As in the triple-axis spectrometer, Bragg reflection from analyser crystals is used to select the neutrons scattered by the sample that will ultimately be detected. However, PRISMA has an array of 16 independent analyser and detector arms instead of just one detector. Each arm of

PRISMA measures along a parabolic path in (Q, ω) space, so generating a two-dimensional scan through (Q, ω) space for each ISIS pulse, in a single setting of the instrument and sample.

Spectrometers for Incoherent INS Spectroscopy

The simplest form of instrument is a filter spectrometer which consists of a monochromator to define the incident neutron energy on the sample and a filter after the sample that only allows neutrons of a given energy to reach the detector. This type of instrument is used at a reactor and is exemplified by IN1BeF at the ILL. The monochromator is the same as for the triple-axis instrument IN1, see **Figure 8**, but the analyser is replaced by a cooled beryllium filter. Beryllium only transmits neutrons with energy of less than 5 meV; higher-energy neutrons are Bragg-scattered out of the beam. The transmission and the sharpness of the cut-off are improved by cooling the filter to below 100 K and it is routinely operated at liquid-nitrogen temperature. Since both the incident and final energies are known, the energy transfer is obtained from eqn [1]. The resolution of the instrument is determined by the bandpass of the filter and the detector response at low energies and by the monochromator at higher energies. Typically the resolution increases from ~ 3 to $\sim 8\%$ of the energy transfer between 20 and 300 meV. The resolution can be improved by using a graphite filter which has a narrower bandpass of ~ 1.5 meV but at the cost of a large decrease in detected flux.

At a spallation source, both indirect- and direct-geometry instruments are used. A schematic of the indirect-geometry spectrometer TOSCA at ISIS is shown in **Figure 9**. A small fraction of the neutrons from the

incident white beam (which extends from 2 meV to beyond 2500 meV) are inelastically scattered by the sample; those that are backscattered through an angle of 135° impinge on a graphite crystal. Only one wavelength (and its harmonics) is Bragg-scattered by the crystal; the remainder pass through the graphite crystal to be absorbed by the shielding. The neutrons at multiples of the fundamental wavelength are removed by the beryllium filter, so only neutrons of ~ 4 meV reach the detectors. The net effect of the combination of the graphite crystal and beryllium filter is to act as a narrow bandpass filter.

The use of a small final energy has two important consequences. Since for most energies $k_i \gg k_f$, it follows that both the magnitude and direction of Q are largely determined by k_i . Thus Q is almost parallel to the incoming neutron beam and perpendicular to the sample plane across virtually the entire energy transfer range. The significance of this is that in order to observe an INS transition, the vibration must have a component of motion parallel to Q . For a randomly oriented (i.e. polycrystalline) sample this condition will be satisfied for all the vibrations and all will be observed. This is not the case for an oriented sample and experiments directly analogous to optical polarization measurements are possible. Further, because Q is independent of k_f there is a unique value of Q for each energy transfer and $Q^2 (\text{\AA}^{-2}) \approx E(\text{meV})/2$. Thus TOSCA (and IN1BeF since it also uses the same final energy) trace out a parabola in (Q, ω) space as shown in **Figure 3b**.

The resolution function varies with energy transfer but is typically 2% of the energy transfer between 2 and 500 meV. The advantages of this system are that it is mechanically simple (there are no moving parts) and it offers excellent resolution across a wide energy range with very low background. Further, the reflection geometry means that the spectrometer is relatively insensitive to multiple scattering (where the neutron undergoes more than one inelastic collision in the sample), so quite large samples (several grams) can be used to improve the count rate.

The pre-eminent direct-geometry spectrometer for this energy range is MARI at ISIS. **Figure 10** shows a schematic of the instrument. Two background-suppression choppers are used; the first is a Nimonic chopper which is used to suppress the prompt pulse of very high energy neutrons and gamma rays that are produced when the proton pulse hits the target. The second is a disc chopper made of borated resin with a single hole. This is designed to suppress the flux of delayed neutrons that are a significant fraction of the background when using a depleted-uranium target.

The core of the instrument is the Fermi chopper. This is a metal drum with a series of slots cut through it. It is magnetically suspended in a vacuum perpendicular to the beam and able to rotate at speeds up to 600 Hz. Thus

Figure 9 Principle of operation of the indirect-geometry spectrometer TOSCA at ISIS. Only two of the 10 analyser/detector modules are shown.

Figure 10 Schematic diagram of the direct-geometry spectrometer MARI at ISIS. M1, M2 and M3 are incident beam monitors.

for most of a rotation, the incoming neutrons are blocked, but at one particular time the slots are parallel to the incoming neutrons and they pass through to the sample. The incident neutron energy is selected by phasing the opening time of the slots with respect to the neutron pulse from the target station. Incident energies in the range 10 to 2000 meV can be selected. The detector bank continuously covers the angular range from 3° to 135° and so is able to map large regions of (Q, ω) space in a single measurement. The energy resolution is between 1 and 2% of the incident energy, and with all the detectors at the same secondary flight path, this resolution is constant for all the detector banks. The large range in Q is essential because phonons and magnons have different Q -dependencies and this is the best way to distinguish between the two sorts of scattering processes.

Three low-efficiency (because of the high neutron flux) detectors are placed in the main beam. The first is placed before the background choppers to monitor the incident flux for the purposes of normalization. The second and third are placed just after the Fermi chopper and behind the sample respectively. These are used to accurately determine the incident energy of the neutrons.

The Energy Range > 1000 meV: Neutron Compton Scattering

In this energy range only spallation sources can provide a sufficient flux of high-energy neutrons. The electron volt spectrometer (eVS) at ISIS is a neutron spectrometer, which uses the high intensity of neutrons in the electronvolt energy range to measure atomic-momentum distributions in a variety of condensed matter systems. When the momentum transfer in the scattering process is sufficiently large (at least 10 times that of the mean atomic momentum), the scattering can be interpreted within the impulse approximation. In this approximation, the scattering is essentially single-atom billiard-ball scattering, which is determined entirely by conservation of momentum and kinetic energy of the atom and the neutron. By measuring the energy and momentum

Figure 11 Schematic diagram of the eVS spectrometer at ISIS. The incident neutrons have velocity v_i , that of the scattered neutrons is v_f and the scattering angle is θ . The moderator-to-sample distance is L_i and the sample-to-detector distance is L_f . The final neutron energy E_f is defined by the analyser foil, which can be either gold or uranium.

change of the neutron, one can determine the momentum component of the target atom along the direction of the scattering vector. This process is neutron Compton scattering.

The instrument is shown schematically in **Figure 11**. eVS is an indirect-geometry inelastic spectrometer. Energy transfers in the 1000–30 000 meV region and momentum transfers between 30 and $200 \text{ \AA}^{-1}$ are achieved using a filter-difference technique. The filter is a thin foil which has a strong nuclear resonance that absorbs neutrons over a narrow band of energy centered at E_f . Two time-of-flight spectra are taken, one with the foil between the sample and detectors and the second with the foil removed. The analyser foils are moved in and out of the scattered beam by computer-controlled pneumatic pistons. One complete cycle is performed every 10 min, that is 5 min with foil in and 5 min with foil out. This is to avoid effects due to long-term changes in the relative efficiency of the detectors, since typical measurement times are 2–12 hr.

The difference between these spectra is due to those neutrons absorbed in the foil and is effectively the spectrum for neutrons scattered with energy E_f . If E_f is known, the momentum and energy transfer can be determined from a measurement of the total time-of-flight t of the neutron from moderator to detector. The

velocity v_i of the scattered neutrons can be calculated from the kinetic energy. The velocity v_i of the incident neutron is determined from a measurement of the neutron time-of-flight t :

$$t = \frac{L_i}{v_i} + \frac{L_f}{v_f} + t_0 \quad [9]$$

where L_i is the distance from source to sample and L_f that from sample to detector. t_0 is an electronic time delay constant. The energy transfer is then given by eqn [6] and the momentum transfer is:

$$Q = m(v_i^2 + v_f^2 + 2v_i v_f \cos \theta)^{0.5} \quad [10]$$

where θ is the scattering angle.

Future Developments

In terms of instrumentation, developments in guide technology will lead to modest gains (factors of two to five) in the flux at the sample. The present trend is towards increasing the area covered by the detectors with corresponding gains in sensitivity and data rate.

INS is a flux-limited technique. Thus major instrumental advances can only be expected when more intense neutron sources become available. These will be spallation sources, since reactor sources, such as the ILL, are already close to the limit of the heat load generated by

the fission process in the reactor core that can be handled. In addition, concerns about nuclear-weapon proliferation (enriched uranium is required for the reactor core) mean that these are politically and environmentally contentious.

MCD	magnetic circular dichroism
UV	ultraviolet

UV-visible absorption spectroscopy is an invaluable method of investigating the structure and the behavior of inorganic compounds, especially the coordination complexes of transition metals, lanthanides, and actinides. Not only are the spectra characteristic of the metal ion, its ligands, and coordination geometry, but they are also informative of its electronic state. Changes in complexation can be followed readily, and the technique is often the one of choice to monitor kinetics of inorganic reactions, complexations, and rearrangements with time, temperature, or other environmental factors.

In the case of chiral compounds, the use of circular dichroism (CD) spectroscopy is invaluable and adds not just an insight into the handedness of the structures but also a further elucidation of their electronic configuration due to the differing selection rules of the spectral transitions. As an extension, by the application of a magnetic field, magnetic circular dichroism (MCD) can yield structural information on both chiral and achiral complexes, especially those with nonsinglet spin states.

Complexes

The classical type of complex has a central metal ion surrounded by coordinating ligands, with little electronic delocalization between them, such that the ligand–metal bonding is essentially ionic. As such, the central metal ion can be assigned a formal charge, as can the ligands where appropriate. However, this is an idealized case and there are many examples where there is significant electron delocalization between the metal ion and the ligands, such that the bonding has a degree of covalent character; such complexes are better described as nonclassical or covalent complexes. Moreover, multicentered complexes, with multiple metal ions, are well represented. There is no *a priori* condition on the phase in which metal complexes can exist and arrays of ions in a crystalline phase can be regarded as simply extended complexes. Thus, a gamut of inorganic systems falls under the broad

description of metal complexes in terms of their spectroscopic behavior.

Most investigations are performed on solutions of complexes. However, studies on the solid crystalline state, with the crystal aligned at specific orientations to ensure excitation to selected states, can aid the interpretation of spectra enormously. As a corollary, the study of oriented crystalline solids by absorption and CD can provide a characterization of the packing arrangement and interactions occurring within the crystal.

Spectral Features

Many of the spectral features of metal complexes in the near-UV (ultraviolet) and visible wavelength regions are primarily derived from the formally electric dipolar forbidden d–d (for transition metals) and f–f (for lanthanides and actinides) transitions of the metal ions. Such ‘metal-centered’ transitions exhibit inherently weak absorptions, the bands corresponding to quadrupole and higher-order electric multipole transitions or magnetic dipole transitions (*cf.* crystal field theory), enhanced by coupled/induced electric dipolar contributions from the ligands (*cf.* ligand polarization theory). It is not unusual for the molar absorptivities (extinction coefficients) of d–d- and f–f-derived bands to be of the order of $\epsilon \approx 0.1\text{--}100\text{ M}^{-1}\text{ cm}^{-1}$. Although generally weak compared to formally electric dipole allowed transitions, the spectral features are distinctive and can be determined with even basic UV-visible absorption spectrometers. However, absorptions primarily derived from the ligands may also be evident and may dominate the weaker features.

In contrast, chiral complexes can yield relatively substantial CD spectra – especially where the features derive from metal-centered magnetic dipole-allowed transitions; the ligands undergo charge transfer (CT) transitions or are in an inherently chiral arrangement and have their own electric dipole-allowed transitions that may take part in exciton coupling (CD exciton coupling is explained further under its own section in this encyclopedia).

Spectral Interpretation and Computation

Although, ideally, theories to rationalize the spectra of metal mixing complexes should fully contain the

confounding aspects of covalency, delocalization, and state (e.g., multielectron multiconfiguration molecular orbital theories), often simpler theories are sufficient for spectral interpretation. In practice, the use of crystal field and ligand polarization theories remains adequate to at least semiquantitatively explain the observed spectral features, provided the metal-ion states are adequately described, i.e., including the effects of spin–orbit coupling and Casimir operators (for lanthanides and actinides).

Although crystal field theory concentrates on the static electrostatic effect of the ligands on the metal ion, ligand polarization theory describes the dynamic effect of coupling between the ligand polarizability and the metal-ion transitions. The combination of crystal field and ligand polarization theories to yield the ‘local systems’ theory enables a good first approximation for rationalization of spectra, in terms of both wavelength and intensity of the absorptions. Moreover, the local systems theory can often be very effective in explaining the CD of chiral metal complexes, both when the CD is derived primarily from the metal-centered transitions and when electronic coupling within the ligands is dominant. Indeed, it provides a sound basis for the ‘hypersensitive’ transitions that display a significant dependence between ligand type and absorption or CD intensity.

[Cobalt (ethylenediamine)₃]³⁺ Example

The details of the absorption and CD strengths can also prove diagnostic in describing the electronic states of a complex. **Table 1** details a classic example of a cobalt *tris*-ethylenediamine complex (derived from the work of Mason 1982). This complex has a chiral, propeller-like structure, the hand of which is determined by the conformation/configuration of the ethylenediamine ligands around the cobalt ion. The $\Lambda(\delta\delta\delta)$ (+)₅₈₉ stereoisomer, one of eight possibilities (four of each hand), is depicted in **Figure 1**. It can be seen that this particular configuration

possesses D₃ symmetry but pseudo-octahedral coordination by the amine nitrogens, which has direct consequences for the spectral features observed both in the solution and the solid state.

It is readily apparent that the different states, described in terms of their pseudo-octahedral (O_h) and D₃ symmetry, impart differing spectral characteristics. In particular, the CT transition, in which charge is transferred from the ligand N–Co σ bond to a metal-centered σ^* antibonding orbital, displays a huge absorption compared to the other transitions, primarily due to its electric transition dipole mechanism. Importantly, this band and magnetic dipole-allowed transition I₁ also display significantly larger CD bands than the other transitions.

Figure 1 $\Lambda(\delta\delta\delta)$ stereoisomer of (+)₅₈₉ [cobalt (ethylenediamine)₃]³⁺, with its central cobalt(III) ion and surrounding three ethylenediamine molecules arranged in a propeller fashion, with D₃ symmetry but pseudo-octahedral coordination by the amine nitrogens. Copyright (2009), with permission from Chiralabs Ltd.

Table 1 UV-visible absorption and circular dichroism solution spectra of (+)₅₈₉ [cobalt (ethylenediamine)₃]³⁺, with terms and symbols relating to the O_h (D₃) symmetry of the complex

Transition	Electronic states	Wavelength (nm)	Absorption ϵ ($M^{-1} cm^{-1}$)	Circular dichroism $\Delta\epsilon$ ($M^{-1} cm^{-1}$)	Kuhn's dissymmetry factor $\Delta\epsilon/\epsilon$
A	$^1A_{1g} \rightarrow ^3T_{1g}$ spin forbidden	740	0.3	– 0.002	– 0.007
B	$^1A_{1g} \rightarrow ^3T_{2g}$ spin forbidden	590	1	+ 0.025	+ 0.025
I ₁	$^1A_{1g} \rightarrow ^1T_{1g}$ (1A_2) spin allowed, magnetic dipole allowed	470	84	+ 1.9	+ 0.02
I ₂	$^1A_{1g} \rightarrow ^1T_{1g}$ (1E) spin allowed, magnetic dipole allowed			– 0.17	
II ₁	$^1A_{1g} \rightarrow ^1T_{2g}$ (1A_1) spin allowed, magnetic dipole forbidden	340	74	+ 0.25	+ 0.003
II ₂	$^1A_{1g} \rightarrow ^1T_{2g}$ (1E) spin allowed, magnetic dipole allowed				
CT	$\sigma(N) \rightarrow \sigma^*(Co)$ charge transfer	210	15 000	– 31	– 0.002

Notably, from solid-state studies in which only certain excited states are accessed by judicious choice of crystal orientation, it can be seen that the I_1 and I_2 CD bands are substantially larger than appears in solution, their apparent magnitude diminished due to cancellation of their oppositely signed CD intensities.

The literature on the absorption and CD spectroscopy of inorganic complexes has a long history and is extensive; the reader is directed to the review articles indicated in the Further Reading section for both a historical and current perspective. The reader is also directed to the other articles in this encyclopedia covering UV-visible absorption, CD, and MCD spectroscopies in general.

Introduction

X-ray diffraction from the solid state is a fundamental technique for the characterization of synthetic and natural materials. Since the discovery of Bragg-type X-ray diffraction from periodic crystal lattices, the technique has proven an essential tool for (1) the identification of crystalline compounds, (2) the quantitative analysis of polyphasic mixtures, (3) the study of the long-range atomic structure of crystals, including detailed charge density studies, and (4) the physical analysis of crystalline aggregates, including orientation texture, crystallite size distribution, and lattice microstrain effects. Such routine applications have developed during the first half of the twentieth century into standard analysis procedures, and during the last decades they became so widely utilized that data are now available for most known inorganic compounds and minerals, to the extent that electronic databases are now accessible for automatic identification and rapid retrieval of crystallographic and structural information of crystalline substances.

The focus of the modern crystallographic research on inorganic solids is the interpretation of the physical and chemical properties of materials in terms of their ideal or defective atomic structure, and the transfer of the acquired crystal chemical knowledge to the engineering of solid-state compounds with novel technological properties. The years since the mid-1980s have also witnessed the development of dedicated second and third generation synchrotron radiation sources in the region of hard X-rays. The availability of brilliant, polarized and collimated synchrotron radiation beams with a wavelength that is tunable over a wide spectral range has made a number of interesting advances possible in materials characterization. State-of-the-art investigations of inorganic compounds and minerals by synchrotron X-ray diffraction include: *in situ* dynamic diffraction of kinetic processes and phase transformations, structural characterization of compounds at ultrahigh pressures, and use of resonant scattering effects for element-selective structural analysis.

X-ray Diffraction Analysis in the Laboratory

X-ray diffraction (XRD) data collection and analysis is routinely performed in any laboratory dealing with inorganic

or mineral compounds. Samples are commonly in the form of small single crystals, polycrystalline aggregates (powders), or oriented specimens (fibres, thin films, polished surfaces). The experimental techniques and the data analysis methods to be applied may therefore vary depending on the physical state and the chemical composition of the sample, besides of course the nature of the requested information. Typical laboratory applications in inorganic chemistry, solid-state physics and mineralogy may involve: (1) identification of unknown crystalline phases, (2) quantification of phase abundance in polycrystalline mixtures, (3) crystal structure determination and refinement, and (4) physical analysis of the sample in terms of crystallite size, lattice microstrain, or orientation texture of the crystal domains. On one hand, the mineralogist usually employs X-ray diffraction to identify and classify mineral specimens, to quantify mineral phases in raw materials for industrial use, or to characterize the temperature–pressure–time history of a rock through the detailed analysis of the crystal structure of the phases present in the mineral assemblage. On the other hand, the inorganic chemist frequently characterizes by X-ray diffraction the products of synthesis reactions in an attempt to refine the synthesis processes or produce new materials with novel structural and physical properties.

The experimental apparatus commonly involve a sealed-tube or rotating-anode X-ray source, a 2-circle (for powders) or a 4-circle (for single crystals) automated diffractometer for sample orientation with respect to the incident beam, and one or more detector banks for detection of the diffracted signal. The angular position, the integrated intensity, and the peak profile shape of the diffracted signal are important for the subsequent analysis.

Phase Identification

Powder X-ray diffraction patterns are the fingerprint of all crystalline substances. The technique is a rapid and powerful tool for identification of all crystalline compounds, and it is especially valuable in the presence of polymorphs or quasi-isochemical compounds, where chemical techniques cannot be applied. The data collection time of a medium-resolution powder diffraction pattern for identification purposes is typically of the order of 20–30 min. Identification of the unknowns in a compound composed of a few phases is a straight-forward automatic procedure in which the Bragg

diffraction peaks in the observed pattern are matched against the reported powder diffraction patterns of all known crystalline substances in the powder diffraction file. Advanced computer software is available for such applications.

If the investigated material is composed of a large number of phases, then the identification process can be more complicated due to substantial overlap of the Bragg peaks related to the different phases. Chemical information on the compound of interest may in this case help in defining subsets of phases from the database containing particular chemical elements. Subsets search may be more successful than the search performed on the whole database, although it requires prior knowledge of information on the sample.

Quantitative Phase Analysis

Quantification of the relative abundance of crystalline phases in a multiphase mixture is an everyday problem in a wide range of applications. Common examples are: evaluation of the yield in inorganic synthesis and catalytic processes, characterization of raw mineral materials for industrial processes, quality check of fired ceramic products, and many more. While in most cases the required accuracy level of the analysis is a few percent at best, in particular cases such as in the quantification of phase contaminants in technologically important materials, or of hazardous and toxic phases in environmentally dispersed aerosols, the required level of accuracy must be substantially lower than 1 wt% relative abundance. Accuracy levels of 2–3 wt% are commonly reached if standard procedures of quantitative phase analysis by diffraction data are properly performed. Generally employed analytical methods include: the internal or external standard method, the matrix flushing method, and the reference intensity ratio method. The availability of analysis techniques of powder diffraction data based on full-profile (Rietveld method), originally developed for structural analysis, has had a great impact in the area of quantitative analysis: if the crystallographic structure of the phases present in the polycrystalline mixture are known, then the complete simulation of the diffraction pattern provides an easy standardless method for accurate quantification of all phases. The major advantage is that only one powder diffraction pattern is needed, with no need for standard addition or laborious external calibration of the peak intensities. **Figure 1** shows the observed, calculated and difference powder diffraction patterns relative to the quantitative analysis of a polycrystalline specimen composed of three standard phases, performed using the standardless Rietveld technique. Estimated standard deviations of relative proportions of all phases are in the range 0.1–0.2 wt%.

If the diffraction data are of above-average quality, the full-profile method can easily allow quantification of

Figure 1 Quantitative phase analysis of a polycrystalline mixture containing three phases performed by the Rietveld method. Selected portions of the observed (crosses) and calculated (solid line) X-ray powder diffraction patterns are shown. The vertical marks indicate the position of the single Bragg peaks.

crystalline phases well below the 1 wt% accuracy level. Advanced nonroutine application of the full-profile technique involves modelling of anisotropic Bragg peak broadening for the quantification of defective or disordered crystal phases. The combination of the full-profile Rietveld analysis with the addition of a known quantity of an internal standard in the mixture provides a simple and reliable method for estimation of the amorphous phase in samples containing noncrystalline components. The accuracy and reliability levels reached by modern methods of quantitative phase analysis based on powder diffractometry commonly exceed the specifications required by phase quantification in traditional and advanced industrial materials.

Crystal Structure Analysis

The analysis of the atomic structure of crystals by diffraction is one of the more developed applications in the whole field of diffraction. Although often used as a simple, rapid technique for molecular structure determination, the full analysis of the crystal structure by X-ray diffraction indeed represents a powerful tool for the

detailed interpretation of the relationship between the long-range atomic arrangement and the physicochemical properties in any solid-state material. Advances in the preparation, engineering and characterization of high-technology materials, such as high- T_c superconducting oxides and fullerenes, could hardly have been achieved without the accurate study of their crystal structure; and the long list of presently known synthetic microporous compounds widely used in catalysis would be much shorter were it not for the detailed structural data obtained on aluminosilicate zeolite minerals.

The standard crystallographic description of the atomic arrangement in a crystal includes the definition of a translation unit cell with its symmetry properties (Bravais lattice type and space group symmetry), the fractional coordinates of each crystallographic position together with the occupancy factor of each chemical species located on it, and its atomic displacement parameters (related to the probability density function of the electron distribution). Standard crystallographic descriptions as such are now available for most known solid-state compounds: the primary reference sources for inorganic crystals and minerals are the Structure Reports (in printed form) and the Inorganic Crystal Structure Database (in CD-ROM form). A number of comprehensive monographs review the essential concepts of chemical bonding in crystals and the classification of basic structural types. The vast majority of structural information has been derived from single-crystal diffraction studies performed with standard laboratory apparatus at room temperature and pressure, although in recent years a growing number of inorganic crystal structure data has resulted from diffraction studies performed on polycrystalline samples using the full-profile Rietveld techniques of analysis. Equilibrium studies at nonambient temperature or pressure, and studies of slow kinetic processes are also accessible in modern X-ray laboratories, both using single-crystal and powder specimens.

The standard crystal structure description of a compound is commonly aimed at the geometrical analysis of the long-range atomic arrangement in terms of interatomic bond distances and angles, coordination polyhedra, and topological bond connectivity. This is the minimal information required for the correct interpretation of the macroscopic physicochemical properties of the compound at the atomic level. Common applications include the understanding of the solid-state reactivity of inorganic compounds, and the reconstruction of the crystallization and transformation processes, that is the geological record, in minerals.

Sometimes subtle or elusive physical effects in crystals require a deeper understanding of the chemical bonding and the crystallochemical role of the atoms. Examples are the oxygen site vacancies and cation substitutions in high- T_c superconducting materials, the atomic or molecular polarization effects in nonlinear optical materials,

the cation partitioning among sublattice sites in microporous framework structures, or the distinction between atomic static (i.e. site disorder) and dynamic (i.e. anisotropic motion) effects in minerals exhibiting nonideal solid solution behaviour. To face such complex problems, non-standard single crystal structure analysis techniques are available. For example, detailed mapping of the electron density in a crystal can be performed by means of charge density studies, commonly performed by low-temperature (down to a few K) X-ray diffraction in order to minimize atomic thermal vibrations smearing out the density effects due to localized electrons. **Figure 2** shows the detailed mapping of the electron density of the H–O–H plane in the water molecule enclosed in the channel of a porous hydrous sodium aluminosilicate, the natural zeolite natrolite, whose complete structure is shown in **Figure 3**. The charge density distribution is derived from the experimental structure factor amplitudes measured by single-crystal X-ray diffraction. Also shown is the map of the Laplacian of the electron charge density in the same plane. On the basis of a Bader-type analysis the map allows detailed interpretation of the character of the chemical bonds in the crystal structure.

Figure 2 Experimental distribution of the electron charge density (a) in the H–O–H plane of the water molecule in the zeolitic channel of natrolite obtained from single-crystal X-ray diffraction data. Detailed interpretation of the chemical bond features, including the position and character of the critical points, is possible through the analysis of the maps of the Laplacian of the charge density (b).

Figure 3 Projection of the structure of the zeolite natrolite along the orthorhombic c axis, showing the zeolitic channels containing the Na atoms (small circles) and the water molecules forming hydrogen bonds to framework oxygen atoms.

Accurate crystal structure studies can be performed on the same crystal in a wide temperature range and allow extrapolation of the true atomic displacement parameters down to the 0 K temperature region, evaluation of the zero-point energy of the atom, and control of the presence of static subsite disorder effects. **Figure 4** shows selected experimentally determined values of the atomic displacement parameters for the Mg, Si, Al and O atoms in a synthetic pyrope garnet of composition $\text{Mg}_3\text{Al}_2\text{Si}_3\text{O}_{12}$. The deviation of the values at 30 K from the linear fit performed on the atomic displacement values measured above 298 K is due to the contribution of the zero-point energy to the atomic motion. Accurate diffraction data of this kind allow separation of the static and dynamic contributions to the measured atomic displacement, and many also indicate the presence of anharmonic vibrational components, although these effects are more appropriately evaluated using temperature-dependent neutron diffraction data.

Physical Analysis of Crystals and Crystal Aggregates

The basic information concerning the nature of the phases present in a synthetic or natural material, and the ideal models of their crystallographic structures are frequently known. The information of interest for the characterization of the material and the understanding of its crystallochemical behaviour then reside in the physical status

Figure 4 Temperature dependence of selected atomic displacement parameters for the Mg, Si, Al and O atoms in pyrope garnet. Analysis of the displacement parameters obtained from accurate single-crystal diffraction data allows evaluation of the zero-point energy contribution, separation of static and dynamic effects, and detection of anharmonic vibrational contributions to the atomic motion.

of the crystal or crystal aggregate. It is known that many material properties of interest in technological applications are directly related to what we might call the deviation from the 'ideal' crystal, that is the presence in the material of a variety of structural defects at the atomic level, such as doping elements, chemical modulations and stacking faults. These perturbations of the periodic crystal lattice produce effects of various kinds observable in the diffraction signal, that is diffuse scattering, superlattice reflections, commensurate or noncommensurate Bragg peak modulations, peak shifts, peak profile distortions, etc. A substantial part of X-ray crystallography deals with the measurement of the diffraction effects caused by lattice disorder, and their interpretation in terms of structural defects. The whole branch of 'quasicrystallography' is devoted to alloys and solid materials exhibiting diffraction effects incompatible with the standard three-dimensional space group symmetry.

A rapidly developing area of study is the measurement of lattice microstrain in polycrystalline aggregates. It is based on the interpretation of the angular dependence of the broadening of Bragg peak profiles in a powder diffraction pattern. The surface or volume mapping of the distribution of lattice strain gradients in the material yields a variety of information on the presence of residual stresses, developing tensions due to microcracking, local imperfections due to coprecipitated phases, and so on. Furthermore the analysis of the peak profile broadening as

Figure 5 Textured diffraction pattern from a meteoritic chondrule collected using short wavelength synchrotron radiation ($\lambda = 0.5 \text{ \AA}$) and a CCD area detector. The image displays sharp diffraction spots from olivine and pyroxene single crystals, and powder diffraction rings from the polycrystalline matrix of the chondrule.

a function of crystallographic direction (anisotropy of the broadening effects) allows determination of the mean particle size and shape of the crystallites in the compound.

The analysis of the statistical or preferred orientation of the crystallites in solid polycrystalline materials is commonly referred to as texture analysis. Again, the diffraction technique allows the definition of the relationship between a microscopic property, that is the orientation of the crystallites defined as coherent diffraction domains, and the macroscopic physical properties of the crystal aggregate. Texture studies are of course crucial in the characterization of oriented synthetic materials such as cold-rolled metals or oxide thin films, but they are also of great relevance in the study of the formation processes of mineral assemblages. As an example, the texture features of olivine or pyroxene minerals in meteoritic chondrules yield information on the early condensation sequence and cooling history of the meteorite body they belong to. **Figure 5** shows the heavily textured diffraction pattern of chondrule from the Mafra L-4 chondritic meteorite collected using synchrotron radiation and a charge-coupled device (CCD) area detector. The pattern displays at the same time sharp diffraction spots produced by the olivine and pyroxene micro-crystals present within the chondrule, and the inhomogeneous intensity distribution on the diffraction rings produced by the polycrystalline matrix. The example indicates how hard X-rays from synchrotron sources can effectively be used to investigate precious materials in a nondestructive way.

Synchrotron X-ray Diffraction

The availability in recent years of the intense, collimated and energy-tunable X-ray beams emitted by synchrotrons and electron storage rings has had a spectacular impact on most fields related to materials characterization. As a consequence, a number of theoretical and instrumental aspects of spectroscopic techniques have rapidly developed in order to take full advantage of the particular properties of synchrotron radiation. All kinds of laboratory X-ray diffraction experiments described earlier can be performed at synchrotron sources as well, and the results are of significantly higher quality in terms of angle- or energy-resolution and signal-to-noise ratio. Furthermore, since the incident radiation beam is several orders of magnitude more brilliant than the laboratory X-ray beams, the experiments can usually be performed using a much smaller volume of sample (down to few cubic micrometres) or, alternatively, by collecting diffraction data with extremely fast acquisition times (down to the millisecond time range). Finally, several completely new types of experiment, such as those outlined in the following sections, are only possible at synchrotron sources.

Dynamic Diffraction

The study of the evolution of the diffraction signal in a sample during a phase transformation or a chemical reaction involving crystalline phases is defined as dynamic diffraction. The term implies that the sample is studied *in situ* under operating conditions of temperature, pressure, vacuum or controlled atmosphere; and that the diffraction pattern is sampled using acquisition times much shorter than the time the process takes to reach completion. Diffraction experiments under nonambient conditions can be performed on laboratory instrumentation only at thermodynamic equilibrium. Direct determination of the metastable and transient phases present during the reaction path, and measurement of fast kinetics are only possible if dynamic diffraction using synchrotron radiation is employed. Commonly the resolution in reciprocal space (defined as $\Delta d/d$, or the ability to distinguish two closely spaced Bragg diffraction peaks) is not a critical experimental parameter when studying the qualitative aspects of the phase transformations, or for the quantification of phase proportions during the process (for example in kinetics studies). On the other hand, resolution is a crucial factor in the investigation of structural phase changes, where high-quality powder spectra collected in time-resolved mode are required.

A typical dynamic diffraction experiment involves (a) a high X-ray flux incident on the sample, (b) a conditioning chamber around the specimen controlling the

environmental variables, and (c) a fast data acquisition system (i.e. position sensitive or area detectors). Depending on the required $\Delta d/d$ resolution, at synchrotron sources these experimental conditions are easily met using either angle-dispersive or energy-dispersive geometries, that is using monochromatic or polychromatic incident radiation, respectively. The flexible design of a synchrotron experiment also allows simultaneous *in situ* experiments to be carried out, such as XRD and small-angle X-ray scattering, XRD and differential scanning calorimetry, or XRD and X-ray absorption spectroscopy in fast scanning mode. Combined experiments of this kind provide a wealth of information, as they furnish the means of simultaneously investigating the process at different space- or momentum-transfer scales. For example, simultaneous time-resolved X-ray powder diffraction and X-ray absorption spectroscopy performed during a solid-state reaction catalysed by a specific chemical element can provide identification and quantification of all the crystalline phases involved, and at the same time also provide short-range information on the coordination environment of the catalyser element at each stage of the reaction.

Applications of the dynamic diffraction experimental techniques are mostly in the areas of temperature-induced dehydration processes in natural zeolites, hydrothermal crystallization of aluminosilicate and aluminophosphate microporous materials, thermal decomposition of layer silicate minerals, high-temperature synthesis of advanced ceramics, and hydrothermal ion-exchange and conversion processes in synthetic molecular sieves. The time-resolved powder diffraction

pattern relative to the isothermal nucleation and growth process of zeolite-A by the hydrothermal treatment of activated metakaolinite is shown in **Figure 6**.

Although most of the cited studies only imply the qualitative analysis of the transformation, or the simple quantification of the crystalline phases involved in the process in order to properly extract the kinetic parameters, a number of full structural studies have been performed, which allow the complete determination of the structure response to the external gradient applied to the sample.

The case study of the temperature-induced phase transformation in the Ca-rich zeolite mineral garronite is illustrated here to show the large amount of detailed information to be gained by dynamic diffraction studies. The time evolution of the experimental powder diffraction pattern is shown in **Figure 7**. The image was obtained by synchrotron radiation using a gas flow heater, a polycrystalline sample in a glass capillary, and an image plate detector installed on a translating camera. Constant-temperature integration of the image pixels yields a number of powder diffraction histograms for the structure analysis. **Figure 8** shows the Rietveld-analysed powder spectra of phase A at room temperature, and phase B at 170 °C. Full structural analysis of all powder data sets produce a detailed picture of the structure response to dehydration, involving the positional shift and the change in coordination of the Ca cation in zeolitic channels, the progressive distortion of the aluminosilicate tetrahedral framework inducing a space-group change from monoclinic to tetragonal, and ultimately the collapse and amorphization of the structure. **Figure 9**

Figure 6 Time evolution of the powder diffraction pattern of zeolite-A crystallizing from activated metakaolinite under hydrothermal conditions. The original image plate picture is shown as a small figure at the bottom left.

Figure 7 Evolution of the X-ray powder diffraction pattern of the natural zeolite garronite during the temperature-induced dehydration process. The data were collected using synchrotron radiation, a gas flow heater, a capillary sample, and an image plate detector installed on a translating camera.

describes the progression of the process by the measured unit cell parameters and volume, and **Figure 10** shows the distortion of the zeolite channels caused by the contraction of the tetrahedral framework along the c tetragonal direction in phase B, which corresponds to the b monoclinic axis of phase A.

High Pressure Studies

Small volume samples are required to reach ultrahigh pressures (i.e. above 10^2 GPa). Therefore, high-brilliance synchrotron radiation is needed to get a useful diffraction signal out of microsamples. This is the reason why the new techniques of high-pressure diffraction were mostly developed with synchrotron radiation sources. Physics, materials science, and especially mineral physics greatly benefited from such developments, because of the possibility of studying high-pressure-stabilized crystal structures using *in situ* diffraction techniques. Since the earth's and planetary interiors are not directly reachable for sampling, we need laboratory techniques to stabilize

Figure 8 Selected portions of the Rietveld-analysed powder diffraction pattern of the zeolite garronite at 25 (a) and 170 (b) °C. The patterns were integrated from the image plate data shown in **Figure 7**. A full structure analysis of the zeolite as a function of temperature was performed.

Figure 9 Structure evolution of the zeolite garronite during the dehydration process. The unit cell parameters and volume resulted from the Rietveld refinements of all powder diffraction data shown in **Figure 7**. Phase A is monoclinic $12/a$ (circles = cell a ; squares = cell b ; triangles = cell c), phase B is tetragonal $P4_12_12$ (triangles = cell $a = b$; diamonds = cell c) and phase C is also tetragonal $P4_12_12$ (hexagons = cell $a = b$; circles = cell c). It may be noted that the cell volume contraction during the monoclinic–tetragonal phase transition is related to the shortening of the monoclinic b axis alone (corresponding to the c axis of the tetragonal cell). The structure analysis indicates that the framework distortion is related to the change in bond coordination of the Ca cation in the zeolitic cages.

Figure 10 Projections of the crystal structures of garronite: (a) phase A at 25 °C along the [100] monoclinic direction; (b) phase B at 170 °C along the [010] tetragonal direction. The distortion of the zeolitic channels caused by the change in coordination of the Ca atoms is evident.

and characterize the materials satisfying the observed large-scale geophysical (density distribution within the planetary interior, seismic waves velocity) and geochemical (abundance of chemical elements in the solar system, element distribution within the planetary bodies) parameters governing the global planetary processes, such as the thermal flow, the mantle convection regime and the crust plate tectonics.

High-pressure mineral physics therefore is concerned with the characterization of the physical properties and

stability fields of planetary materials under extreme pressure and temperature conditions. For example, conditions present at the centre of the earth are thought to be in excess of 300 GPa and 5000 K. Such conditions can at present be obtained by laser-heated diamond anvil cells or multianvil presses. Emphasis of current *in situ* diffraction studies using synchrotron radiation under extreme conditions is on the definition of the thermodynamic phase stability fields of the crystalline phases possibly present in the earth's mantle and core, on the experimental measurement of the equations of

state in P–V–T space, and in the crystal structure determination of the high-pressure phases.

Resonant Scattering Experiments

A noticeable advantage of synchrotron radiation is the possibility of fine tuning the incident energy over a wide range, typically 5–50 keV for bending magnet radiation from high-energy third-generation synchrotrons (up to 100 keV for wiggler radiation from the same machines) and 2–20 keV for bending magnet radiation from low-energy third-generation synchrotrons. The available energy range covers absorption K-edges of chemical elements from P to the rare earth elements, and L-edges from Rb to the actinides. The wavelength tunability is not only of obvious advantage for X-ray absorption spectroscopy, but it also offers diffraction an increased flexibility through proper exploitation of the resonant scattering effect. The excitation of resonant scattering takes place when diffraction is performed using an incident energy close to that of an absorption edge of a chemical element present in the sample. Under these conditions the atomic scattering factor of the element is modified by a factor (called the anomalous dispersion correction) amounting to several electrons. It is obvious that by performing diffraction studies at different wavelengths in the vicinity of an absorption edge, it is possible to change to scattering contrast between the chemical elements present in the sample, and therefore increase the ability of diffraction to (1) determine the location of the particular element in the structure, or (2) quantify the statistical amount of that element in specific crystallographic sites.

Since an energy shift of the absorption edge is observed depending on the oxidation state of the element, the accurate determination of the energy dependence of the anomalous dispersion term yields information on the valence state of the element present in a crystallographic site, in much the same way as this information is obtained from the chemical shift of the edge in X-ray absorption spectroscopy. However, the information obtained from absorption spectroscopy is averaged over the sample volume, and cannot discriminate between different valence states of the same element simultaneously present on different structural sites, whereas diffraction under

resonant conditions intrinsically yields site-resolved information. The resonance effect is also exploited for the resolution of crystal structures, especially organic macromolecules, using the multiwavelength anomalous dispersion technique.

Diffraction exploiting the resonant scattering effect is generally used in inorganic chemistry and mineralogy to determine the cation partitioning of specific elements among different crystallographic sites, or to evaluate the oxidation state of chemical elements present in specific structural sites. A promising extension of the technique is called diffraction anomalous fine structure spectroscopy, and it involves measurement of the energy dependence of the integrated intensity of particular Bragg diffraction peaks across an absorption edge.

The Interaction of Impurities in Condensed Matter with Light

The optical spectroscopy of impurities in solids and liquids is similar to that of free particles except that interpretation requires an extra interaction to be taken into account, i.e. the influence of the host on the energy levels of the impurity. In other words, the presence of the impurity particle in a particular environment adds an extra term to the Hamiltonian: the crystal field.

There are two components of the crystal field: static, referring to the average position of nearest neighbour particles, and dynamic, referring to their motion. The static crystal field shifts energy levels and lifts degeneracies to cause splittings whilst the dynamic crystal field allows coupling of electronic energy levels to vibrations. In terms of luminescence spectroscopy, the static crystal field is principally responsible for shifting emission wavelengths whilst the dynamic component broadens emission lines into bands of widely varying widths and shapes. Both static and dynamic effects can influence the oscillator strength of the transition and thus the luminescence lifetime. Excited state lifetimes can also be influenced by factors such as nonradiative decay and concentration quenching.

Insulators provide a useful trap for optically active ions due to their transparency in the visible region. Nuclear (vibrational) resonances with electromagnetic radiation take place in the infrared part of the spectrum whilst resonances with bound electrons (from the valence band to the conduction band) are usually in the ultraviolet. Visible radiation therefore interacts with the impurities alone. The role of the host is simply to influence the optical behaviour of the impurity.

Spectroscopic Characteristics of Impurities in Condensed Matter

Lanthanide Ion Doping

The optically active electrons in lanthanide ions are 4f electrons and they are shielded from the influence of the crystal field by the complete 5s and 5p subshells that surround them. Therefore, the static crystal field has only a small effect on the energy levels of lanthanides and is

treated as a perturbation to the free ion states. This perturbation is significant, however. Electric dipole transitions between pure 4f states are parity forbidden (though some of the much weaker magnetic dipole transitions are allowed). The addition of the crystal field term causes weak mixing of 4f states, most importantly with 5d states, so that some electric dipole transitions become weakly allowed. Reducing the symmetry of the crystal field tends to cause greater mixing thus making the optical transitions more intense. At the same time, the *J*-degeneracy of the state is lifted so that the luminescence spectrum of a particular transition appears as a number of closely separated lines such as those shown in **Figure 1a**. The dynamic crystal field is also weakly interacting with lanthanide ion impurities so that phonon-assisted transitions are rarely significant features.

Luminescence studies are particularly useful for lanthanide-activated matter as transitions are often weak thus rendering absorption difficult to measure. Each lanthanide ion has a unique energy level structure so that excitation of such a material will result in a luminescence spectrum characteristic of that impurity ion. Only a small proportion of energy levels luminesce, however. Most decay non-radiatively through multiphonon emission to states at slightly lower energies. The excited electron rapidly tumbles between states until it reaches one that is separated by more than about $1000\text{--}3000\text{ cm}^{-1}$ ($1\text{ eV} \approx 8000\text{ cm}^{-1}$), depending on the system, from the next lowest level. The probability of multiphonon decay is an exponential function of separation so that states with wide gaps to next lowest levels are unlikely to decay nonradiatively. Luminescence is thus emitted from such states. As an example, the energy structure of Nd^{3+} is shown in **Figure 1b**.

Transition Metal Ion Doping

The active electrons in transition metal ions are not shielded by outer subshells and this leads to a much stronger interaction with the crystal field. The Hamiltonian contains the same components as for lanthanides but now the crystal field cannot be treated as a perturbation to the free ion states as this term is similar in strength to the electron–electron interactions and stronger than spin–orbit coupling terms. The resulting wavefunctions are denoted by a nomenclature that derives from group theory.

Figure 1 Luminescence from a typical lanthanide-doped crystal, Nd^{3+} -doped KLiYF_6 . The $^4F_{3/2} \rightarrow ^4I_{11/2}$ luminescence multiplet, most often used as the gain transition in Nd-based lasers, is shown in (a) and the energy level diagram is shown in (b). The total Nd^{3+} multiplet splittings for this host are indicated by the thickness of the boxes, levels that radiate significantly are denoted by small arrows and the $^4F_{3/2} \rightarrow ^4I_{11/2}$ transition is indicated by a long arrow. This luminescence multiplet would normally be expected to be split into no more than six components but the 12 observed indicates that Nd^{3+} substitutes into two different sites in this crystal. The similarity of the spectra due to different site substitution is typical for lanthanides and the energy level diagram in (b) varies very little from host to host.

Plots, known as Tanabe–Sugano diagrams, show how the state energies of transition metal ions vary as a function of crystal field strength. From these plots absorption and luminescence characteristics can be predicted or explained. **Figure 2** shows the Tanabe–Sugano diagram for Cr^{3+} . The dashed line indicates the crystal field strength for aluminium oxide ($\text{Al}_2\text{O}_3:\text{Cr}^{3+}$ is ruby) and it indicates where the excited state energy levels lie relative to the ground state (4A_2). Absorption bands appear resonant with the energy levels, broad in the case of states that are strongly vibronically coupled and narrow for weak electron–phonon coupling. The emission spectrum consists of a single line with some weak vibronically assisted structure regardless of which absorption transition is excited. This is because, as for lanthanides, rapid nonradiative decay prevents luminescence from states that have other levels at energies close below. In this case, narrow band luminescence is seen (the ruby laser transition) but for materials that provide a weaker crystal field environment for Cr^{3+} ions, the 4T_2 state may be at a lower energy than the 2E state making it the emitting level. Much stronger electron–phonon coupling occurs for this transition (as for the reverse $^4A_2 \rightarrow ^4T_2$ (absorption) transition indicated in **Figure 2**) and broad-band emission results.

Colour Centres

Colour centres (or F centres) result from the presence of defects in the structure of a solid, often intentionally induced, for instance by high-energy-photon irradiation. Such treatment causes disruption to the lattice and leads to the production of particular defects. For instance, a single electron can become trapped in an anion vacancy. The Hamiltonian for such a system is considerably different from that of an impurity ion but the resulting eigenenergies give rise to transitions in the optical region of the spectrum. Such a centre is influenced very strongly by the crystal field and so transitions are always strongly coupled to vibrations resulting in very broad absorption and luminescence spectra ($\sim 1000\text{--}4000 \text{ cm}^{-1}$). There is a wide range of different optically active defects and determining the structure of colour centres is difficult using only optical techniques. However, by applying external fields and stresses and making measurements of properties such as polarization and magnetic circular dichroism much can be understood. Of great assistance are magnetic resonance measurements, in particular electron paramagnetic resonance. Such techniques reveal information on the number of electrons present and the symmetry of the colour centre from which structure can be deduced.

Crystals, Glasses and Liquids as Hosts

It might be expected that the various types of condensed matter host will give rise to quite different optical properties for the impurities that they contain. In fact, the

Figure 2 A Tanabe–Sugano diagram for a $3d^3$ impurity ion such as Cr^{3+} . The octahedral crystal field increases along the x-axis and the energy levels split and shift as indicated. For zero crystal field the free ion LS states are indicated on the left. A dashed line indicates the crystal field strength relevant to ruby. The energy levels indicated appear in the absorption spectrum shown on the right. Luminescence is only from the lowest lying excited state, ${}^2\text{E}$. For materials that provide weaker field environments the ${}^4\text{T}_2$ state is lower and much broader bandwidth emission is obtained. Reproduced with permission of Oxford University Press from Henderson B and Imbusch GF (1989) *Optical Spectroscopy of Inorganic Solids*. Oxford: Clarendon Press.

impurity has a much stronger influence than the host. This is especially true for lanthanide ions. These are not greatly influenced by their surroundings so that a change of environment does not make very much difference to optical behaviour. Splittings between J -levels will vary between hosts and transition strengths will also vary whilst remaining relatively weak.

Transition metal ions are more strongly influenced by environment, for instance Cr^{3+} ions decay via entirely different transitions depending on crystal field strength. Generally, transition metal ions will have an energetically preferred orientation. The energy of solvation of the Cr^{3+} ion is lowest when octahedrally coordinated, in solids and liquids. In aqueous solution six water molecules are arranged about the chromium ion. In glasses lack of long-range order means that the solvation energy of the Cr^{3+} ion can be minimized without influencing the overall structure of the host so that, again, Cr^{3+} ions become octahedrally coordinated, this time surrounded by the dominant anions (often fluoride or oxide ions). In crystals the situation is somewhat different. The lattice energy of the host is minimized by long-range order so that considerations of the solvation energy of the Cr^{3+} ion are of

much less significance. If there is a suitable octahedral site (or somewhat distorted octahedral site) for the Cr^{3+} ion then substitution can occur. If not, then the chromium ion may enter as an alternative valence (e.g. Cr^{4+} in a tetragonal site) or may not enter the lattice at all. In fluids and glasses it is more likely that a transition metal ion can find its energetically preferred orientation due to the impurity ion's greater influence on its own neighbourhood. In crystals, transition metal ions often enter more distorted sites according to availability and this sometimes leads to more unusual optical properties such as large energy level splittings or transition strengths.

The main difference between spectra obtained in different classes of hosts is in the broadening of features. In a perfect crystal every impurity ion would experience the same potential due to neighbour particles so that each ion would behave in a spectroscopically identical way. Spectra would not be broadened, other than by homogeneous and vibrational effects, and would consist of very narrow zero phonon lines and phonon side bands. Perfect crystals do not exist and inhomogeneous broadening due to variation in crystal field contributions to the Hamiltonian is always present (see **Figure 3**). This is not always apparent at room

Figure 3 A typical zero phonon luminescence line from a bulk sample would appear as in (a) with a typical inhomogeneous width (Γ) of $1\text{--}10\text{ cm}^{-1}$. As the number of emitting impurities decreases, the smooth line shape typical of a large distribution is lost (b) and eventually the contributions of individual homogeneously broadened contributions appear in the wings (c). The homogeneous width is exaggerated by a factor of about 10^4 for temperatures of less than about 4 K.

temperature when homogeneous broadening dominates in most systems but below about 100 K, in solids, inhomogeneous broadening has a significant influence. In glasses and liquids inhomogeneous broadening is usually more significant. The local environment of the impurity ion is influenced less strictly by the host and the lack of order leads to a much greater range of environments and thus greater broadening of spectral features.

Lanthanide doped crystals typically give rise to luminescence multiplets with spreads in energy of around $100\text{--}1000\text{ cm}^{-1}$. Line widths of individual features at low temperatures tend to be around 100 times narrower than this. In glasses and liquids, however, the effect of variation in environment causes luminescence to be emitted in bands that encompass the whole of the multiplet and individual lines cannot usually be resolved. Such bandwidths are not greatly broadened beyond the multiplet widths of crystals, however.

The zero phonon lines of transition metal ions behave similarly to those of lanthanides but phonon side bands are more evident. Such is the extent of broadening due to electron–phonon coupling that the influence of environment is proportionally much smaller. It is unusual to see disorder-induced broadening of phonon-assisted bands by more than a factor of two.

The greatest broadening effects are actually observed in substitutionally disordered crystals. Substitutional disorder in crystals occurs when two or more constituent ions have interchangeable lattice positions. Whilst the stoichiometry and periodicity of the crystal is maintained, the local

environment varies throughout the structure. Optically active impurity ions experience different crystal fields as a result of this local variation. Inhomogeneous broadening through substitutional disorder is strongest when it is the nearest neighbour ions that are randomly occupied. For instance, the ${}^7F_0 \rightarrow {}^5D_0$ transition of Sm^{2+} in BaFCl is broadened by a factor of 30 at low temperatures through the addition of bromine to the melt to produce $\text{BaFCl}_{0.5}\text{Br}_{0.5}$. Such is the magnitude of the effect that inhomogeneous broadening dominates homogenous broadening up to temperatures in excess of 300 K. This discovery prompted a successful search for room temperature persistent spectral hole-burning materials (see below).

Techniques Used to Study Optically Activated Condensed Matter

Very simple methods can be used to obtain useful information on the optical behaviour of impurity doped condensed matter. The first step in the characterization of such a material is usually to measure its absorption spectrum in the region of about $0.3\text{--}1\text{ }\mu\text{m}$. Such measurements are often sufficient to identify the active impurities and to provide some information on their environment. For crystalline hosts, the polarization of absorption spectra can be analysed to draw conclusions on site symmetries and crystal field parameters (see Figure 4).

As well as ground state absorption measurements, it is often also useful to know the absorption characteristics of

Figure 4 The absorption spectrum of the $^4I_{9/2} \rightarrow ^4F_{5/2} + ^2H_{9/2}$ and $^4I_{9/2} \rightarrow ^4F_{3/2}$ transitions (see **Figure 1b**) in Nd^{3+} -doped KLiF_5 measured in two different polarizations at 77 K. Similar variations in intensities within multiplets are observed in luminescence spectra.

excited metastable states, particularly for potential laser gain media. Such measurements are considerably more difficult than ground state measurements because it is necessary to maintain a significant excited state population. The experimental arrangement required to obtain such spectra requires two excitation sources, a powerful beam to excite the material and a weaker probe to measure the absorption immediately after the excitation pulse.

There are some materials for which even ground state absorption is too weak to measure. A method that provides equivalent information is zero-order excitation spectroscopy. Emission at all wavelengths is directed to a detector without dispersion. A time delay is required to prevent excitation light from swamping the signal. Ideally, this is achieved using a pulsed laser and gated detector but other systems also work, such as asynchronous choppers in a continuous beam. By varying the wavelength of the exciting beam and recording the strength of emission at all wavelengths a spectrum equivalent to that of the absorption of all luminescent centres is recorded.

The zero-order excitation spectrum reveals the wavelengths at which the material can be excited to obtain luminescence. The luminescence spectrum can be recorded by exciting at one of these wavelengths and

dispersing the emission using a monochromator. When emission is weak a chopper can be placed in the excitation beam to produce a modulated intensity that a lock-in amplifier can detect.

Generally, excited ions step between energetically nearby states nonradiatively until a large gap is encountered from which radiative transitions occur. In a crystal in which all impurity ions occupy equivalent sites similar spectra are obtained regardless of which absorption transition is excited, unless there are two or more widely separated emitting states. In the latter case a different luminescence spectrum is obtained for each emitting state when excitation is resonant with levels between it and the next highest emitting state (see **Figure 1**).

Occasionally, the same impurity ion may substitute into two or more crystallographically different impurity sites within a single host. Each will normally have its own luminescence characteristics so that excitation at particular wavelengths may excite one set of ions and not the other when absorption bands do not overlap. This occurs most often for materials with narrow band absorption spectra, in particular lanthanides, and different luminescence spectra will result depending on the selected absorption feature (see **Figure 5**). Energy transfer between sites may cause both sites to emit under some circumstances.

Figure 5 Selective excitation spectra for the ${}^2P_{3/2} \rightarrow {}^4I_{13/2}$ transition in Nd^{3+} -doped KLiYF_6 . The top two spectra are produced by exciting the material at wavelengths that result in luminescence from only one of the two Nd^{3+} substitutional sites whereas the bottom spectrum is excited at a wavelength that excites both. This is an example of upconversion as the exciting photon energy is lower than the output photon energy. Site selection in this case occurs during excited state absorption from the ${}^4F_{3/2}$ state. Reproduced with permission of Elsevier Science from Russell DL, Henderson B, Chai BH, Nicholls JFH, and Holliday K (1997) *Optics Communications* 134: 398–406.

In hosts in which a distribution of sites exist, shifts in emission bands result from excitation at different energies within an absorption band. The site distribution may be broadened by variation in crystal field strength or in electron–phonon coupling strength and measurements of the shift of the emission band as a function of excitation energy allow the contributions of each distribution to be quantified. **Figure 6** shows the luminescence spectrum of Cr^{3+} -doped strontium gallogermanate, a substitutionally disordered crystal that gives rise to luminescence via both the ${}^2E \rightarrow {}^4A_2$ and ${}^4T_2 \rightarrow {}^4A_2$ transitions due to a large variation in crystal field strength that causes the emitting state to vary between sites (see **Figure 2**).

Selective excitation techniques may be used to make high-resolution measurements. At low temperatures where inhomogeneous broadening dominates, it is possible to use a highly monochromatic excitation source such as a single frequency dye laser to select a subset of impurities, each of which contributes to the same portion of a spectral line. The resolution of spectral measurements is then, in principle, limited by the homogeneous line width. Below 10 K this is typically of the order of 10^6 times smaller than the inhomogeneous line width.

In the absence of energy transfer, exciting a subset of impurities will result in luminescence from only this

Figure 6 The luminescence spectrum of Cr^{3+} -doped $\text{Sr}_3\text{Ga}_2\text{Ge}_4\text{O}_{14}$ which decays via two different transitions due to the large variation in crystal fields experienced by the Cr^{3+} ions (see **Figure 2**). The structure in the ${}^4T_2 \rightarrow {}^4A_2$ band is instrumental noise.

subset. Single mode dye lasers can routinely provide excitation line widths of 1 MHz and solid state tunable lasers can do considerably better. A typical monochromator or scanning Fabry–Perot etalon cannot reach such resolutions and so the detected emission is limited by the resolution of the dispersion apparatus. Nevertheless, fluorescence line narrowing (see **Figure 7e**) can reveal information on, for instance, ground state splittings, that are normally hidden beneath the inhomogeneous broadening of the transition. Fluorescence line narrowing is usually employed on purely electronic transitions but is quite generally applicable to these.

For certain materials the excitation process results in a subsequent decrease in absorption at the same wavelength. This selective bleaching may persist indefinitely and can occur through a variety of mechanisms, all of which rely on the removal of a proportion of absorbing impurities from resonance. The spectral hole line shape may then be recorded by scanning the excitation wavelength and the spectral resolution is determined by the laser line width alone, making possible measurements of homogenous line widths. Persistent spectral hole-burning (see **Figure 7**) is not a universal phenomenon but does occur for a wide range of materials. Amongst the most common mechanisms for impurities to be removed from resonance are oxidation (e.g. $\text{Sm}^{2+} \rightarrow \text{Sm}^{3+}$), motion of the impurity ion within the lattice (or alternatively a redistribution of the local environment about the impurity ion) and redistribution of ground state nuclear spins. The persistence of the spectral hole allows perturbation experiments (e.g. Stark effect, Zeeman effect,

Figure 7 Schematic illustration of two high-resolution laser techniques. On the left is a technique that relies on excitation (or absorption) spectroscopy, spectral hole-burning, which is therefore instrumentally limited only by laser line width. On the right, fluorescence line narrowing is indicated, a technique that involves recording an emission spectrum which is therefore limited both by laser line width and by dispersion resolution.

stress effects) to be undertaken with much greater sensitivity than is possible when observing the effects of very high fields on entire inhomogeneously broadened spectral lines.

The ultimate way to unambiguously examine the behaviour of impurities and defects in host matrices is to detect single chromophores (see **Figure 3**). The principle underpinning this luminescence excitation technique relies, like spectral hole-burning, on the reduction of the homogenous line width of the zero phonon electronic transition with decreasing temperature. Inhomogeneous broadening is insensitive to temperature and so the overlap of spectral lines from individual chromophores decreases with decreasing temperature. If the sample is then diluted until the concentration is sufficiently low, the superposition of absorption contributions is no longer smooth. This is known as statistical fine structure. As the sample is diluted further, single chromophores will have no effective absorptive spectral overlap with other chromophores in the wings of the absorption line and any emission detected will correspond to this single atom, ion, molecule or defect centre. With continuing dilution, single chromophores may be detected closer to the inhomogeneous line centre. To date, this technique has only been applied to dye molecules in organic hosts but could in principle be applied to any impurity doped solid that has a zero phonon electronic transition.

Luminescence Phenomena Studied in Optically Activated Condensed Matter

The interaction between impurity (or defect) and host determines the energy levels of the optically active species and so the most obvious application of luminescence spectroscopy to condensed matter is determination of site structure. The magnitude of the splittings of electronic levels is determined by the strength of the crystal field and the extent to which degeneracies are lifted is determined by the site symmetry of the crystal field. Simple absorption, excitation or luminescence spectra can thus reveal such information through application of group theoretical analytical techniques and this can be enhanced with data from perturbation experiments. Clearly these methods are most useful for materials in which the electron-phonon coupling is weak so that zero phonon lines dominate and hence lanthanide (and some transition metal) doped crystals are most appropriate for such a study. Doping impurities into hosts is not a sensible method to study the pure host as the presence of the impurity can distort the local lattice structure, but more general conclusions on the host (such as the extent of crystallinity) can be reached by studying parameters such as the broadening of transitions.

When electron-phonon coupling is strong, so that zero phonon lines are weak, other techniques can be used

Figure 8 Luminescence spectra of the ${}^4T_2 \rightarrow {}^4A_2$ transition at indicated temperatures in Cr^{3+} -doped $LiCaAlF_6$ (LiCAF) and $LiSrAlF_6$ (LiSAF), host crystals that are isostructural but with slightly different unit cell sizes.

to determine information about site structure. Polarized measurements of features in absorption, excitation and luminescence spectra provide direct evidence of the symmetries of the wavefunctions involved in these transitions and this leads to information on site structure. Usually this information is best used in conjunction with other spectroscopic techniques such as electron paramagnetic resonance (detected either directly or optically). The form of a phonon-assisted sideband can itself reveal information on site structure, especially the extent of the local deformation that occurs when the impurity is excited to a higher electronic state. **Figure 8** compares the luminescence spectra of Cr^{3+} impurity ions in $LiCaAlF_6$ and $LiSrAlF_6$, crystals that are isomorphous but with different unit cell sizes. The decreased bandwidth and increased structure associated with the $LiCaAlF_6$ spectrum indicates weaker electron–phonon coupling and a smaller excited state deformation. Again, group theoretical analysis can be applied to such results to obtain detailed information. For $LiCaAlF_6$ specific phonon transitions can be identified at low temperatures. Application of polarized spectroscopy to these features and comparison with Raman spectra can provide further information on the details of electron–phonon coupling and site structure.

Upconversion refers to a process in which a material emits photons of higher energy than those with which it is excited (see **Figure 5**). It is a phenomenon most commonly associated with lanthanide-doped materials

and can take place through a variety of mechanisms including cross relaxation, energy transfer, excited state absorption and two-photon absorption. Studying the dynamics of such systems using time resolved techniques is an excellent method for exploring these processes within solids. Variation of doping levels and pump intensities help to determine exactly which processes dominate and the way in which they operate.

Fluorescence line narrowing is also a useful technique for studying energy transfer, in particular when measurements are time resolved. When a subsection of the impurities in a material is excited via energy selection it is the same impurities that luminesce, except when energy transfer takes place. If time-resolved spectra are taken, the rate at which energy transfer processes progress can be determined as the line broadens. The line narrowing that results from energy selection can also be used to resolve small splittings in either the ground or excited state of the material. Cr^{3+} -doped strontium gallogermanate provides a nice example of this. **Figure 9** shows spectra obtained by exciting the ${}^4A_2 \rightarrow {}^2E$ electronic transition and recording emission from the reverse transition. By using relatively low resolution dispersion (a monochromator) the relatively large excited state splitting ($\sim 20\text{ cm}^{-1}$) can be measured, but when detecting using a Fabry–Perot etalon the ground state splitting ($\sim 2\text{ cm}^{-1}$) is revealed.

Spectral hole-burning has been used to investigate a wide variety of phenomena that includes impurity and defect structure, electron–nuclear interactions, spin–spin cross relaxation, tunnelling processes, optical dephasing, spectral diffusion in glasses, electron–phonon coupling and the behaviour of special materials such as biological compounds (involved in photosynthesis for example) and thin films. Much fuller details are given elsewhere in this encyclopedia.

A range of phenomena can be studied in solution, though generally only the simpler techniques discussed above are available due to the dynamics of the liquid phase. Measurements of luminescent lifetime can be interpreted in terms of the coordination number of the optically active solvated ion. Quenching and sensitizing of luminescence by the manipulation of the solution (e.g. addition of other species, change of acidity, etc.) is another common area of investigation. Generally, such effects are chemical in nature. The luminescent ion forms a bond, either loosely with surrounding solvent molecules or more strongly with ligand species. Quenching or sensitization takes place depending on the interaction between the optically active ion and its immediate surroundings. Much of this area of study is related to organic chemistry in that large organometallic ions are formed in solution and it is their behaviour that is being probed in optical experiments. This is discussed further elsewhere in the encyclopedia.

Figure 9 Fluorescence line narrowed spectra of the ${}^2E \rightarrow {}^4A_2$ transition in Cr^{3+} -doped $\text{Sr}_3\text{Ga}_2\text{Ge}_4\text{O}_{14}$ (see **Figure 6**). When dispersing emission using a monochromator (long spectrum) the excited state (2E) splitting of $\sim 20 \text{ cm}^{-1}$ is observed. When dispersing emission using a Fabry–Perot etalon (internal spectrum) the ground state (4A_2) splitting of $\sim 2 \text{ cm}^{-1}$ is observed. Technological Applications of Optically Activated Condensed Matter

To investigate materials such as laser gain media only simple experimental techniques are usually required. To evaluate the potential of a new material in a technological application it is often sufficient to measure absorption and emission spectra along with luminescence lifetimes, though it is desirable to also have an indication of relevant loss mechanisms. These include nonradiative decay, excited state absorption and energy transfer. The result of significant nonradiative decay is indicated by variations in luminescence intensity and lifetime as a function of temperature whereas energy transfer can be investigated using techniques such as time-resolved fluorescence line narrowing and upconversion. The results of studies of laser gain media and related materials has led to the concept of ‘crystal field engineering’ where the ideal combination of impurity and crystal field for any particular application can be calculated and then created through careful choice of host. In reality there is always feedback between spectroscopic interpretation and technological implementation.

The bestknown materials that have been developed are for implementation in lasers, either as gain media or as saturable absorbers. The first laser gain medium was ruby (see **Figure 2**), providing single wavelength output in the visible part of the spectrum. Neodymium-based lasers have now largely replaced ruby as the industrial laser of choice. The ${}^4F_{3/2} \rightarrow {}^4I_{11/2}$ electronic transition (see **Figure 1**) provides laser emission just beyond $1 \mu\text{m}$ in a number of

hosts, most notably in yttrium aluminium garnet ($\text{Y}_3\text{Al}_5\text{O}_{12}$). More recently, tunable laser gain media such as Ti^{3+} -doped sapphire (Al_2O_3) and Cr^{3+} -doped LiSrAlF_6 (**Figure 8**) have been developed and these provide variable wavelength outputs across the near-infrared. Both systems are based on vibronically assisted luminescence bands that arise due to strong electron–phonon coupling. Many other laser systems have been developed, including those that use lanthanide ion doped optical fibres as the gain medium and others that are able to sustain oscillation on upconversion transitions.

The much greater inhomogeneous broadening that results from disorder in glasses has also been exploited, for instance in erbium-doped fibre amplifiers. In these devices a small part of an optical fibre communication system is doped with erbium. A diode laser is coupled into the fibre and pumps the erbium ions to an excited metastable state. As the signal passes through this part of the fibre it is amplified through stimulated emission. Using a glass host for this purpose broadens the transition and allows broad bandwidth operation.

There are more speculative applications associated with some of the more advanced techniques. For instance, spectral hole-burning has been suggested as a high density optical storage medium whereby binary digits are indicated by the presence or absence of a hole at any given wavelength thus adding wavelength to spatial position in a compact disc-like memory. Extensions to this idea include the storage of images as spectral holes through the production of wavelength multiplexed holographic gratings and the combination of these images through Stark effect splittings of spectral holes to produce an optical parallel

processor. These ideas have been demonstrated in principle but, to date, are only feasible when the sample is maintained at very low temperatures.

Amongst the more important applications of luminescence spectroscopy in the liquid phase is the detection of small amounts of impurities in naturally occurring solutions such as rivers and groundwater. A full knowledge of quenching and sensitization effects are required to be able to solve these problems. Of particular importance in this area is the detection of pollution and especially radioactive pollution that can be dangerous in very small quantities. Actinides are generally strongly luminescent and so spectroscopic techniques are very effective.

Introduction

The origin and evolution of life has long fascinated mankind. It is directly tied to the abiotic formation and chemical history of the biogenic elements, in particular H, C, N, O, P and S. The evolution of most elements starts with nucleosynthesis inside the fiery cauldrons of stellar interiors. Eventually, these elements are injected into the interstellar medium, either through violent supernova explosions or through more gentle stellar winds, which terminate the life of most stars. Thus, stellar formation, evolution and death are intimately connected, as the ashes of one generation of stars become the building blocks of the next generation. Much of the expelled material is in the form of molecules, ranging from the simple diatomics such as molecular hydrogen (H_2) and carbon monoxide (CO) to more complex species such as polycyclic aromatic hydrocarbons (PAHs) and fullerenes (C_{60}), or in the form of small (≈ 100 nm) dust grains – carbon based (i.e. soot and silicon carbide) and silicates (aluminium oxide, olivine, enstatite). In evolution from their birth sites, through the interstellar medium, until their incorporation into new planetary systems, these elements undergo a complex chemical history. Various processes cycle the material from the gas phase to the solid phase and from one chemical compound to another. Understanding this history and its relation to the origin of life is one of the key questions of modern astrophysics.

The most important tool for astronomers to understand the origin and evolution of the molecular universe is spectroscopy. This includes studies of the rotational emission spectrum of the cold interstellar gases in the microwave wavelength region. Near bright stars, vibrational modes can be excited through fluorescence. Electronic spectra are predominantly measured through absorption spectroscopy against a bright background source. Each of these wavelength regions has its own techniques and provides unique information on interstellar molecules. Together they point to a chemically diverse and active molecular universe. Each of these techniques and their results will be briefly summarized.

Rotational Spectroscopy

Hundreds of pure rotational lines of a variety of molecules have been detected in the interstellar medium,

most of them in emission but some also in absorption. These lines occur throughout the millimetre, centimetre and decametre wavelength region of the spectrum and are detected using radio antennas and heterodyne detection techniques at spectral resolutions of typically 300 000. At submillimetre and far-infrared wavelengths, the atmosphere is not very transparent (**Figure 1**) and telescopes are located on high, dry sites, on airborne platforms or in space. **Figure 2** shows the results of a line survey of a star-forming region in the Orion constellation, illustrating the richness of the spectrum and the diversity of the molecules contributing. Many of these rotational lines are bright enough to map the spatial distribution of the molecular emission. Such maps can be intercompared to study the interrelationship of various molecules. Also, they can be compared to maps of (newborn) stars to determine the interaction of stars with the surrounding (natal) molecular gas.

Similar spectral and spatial studies have been performed for the ejecta of stars in the later stages of their life to probe their molecular composition and evolution. Because the central star heats the gas to warm temperatures (up to 1000 K), rotational lines in the far-infrared can be excited as well. **Figure 3** shows the far-infrared spectrum of such a star, IRC 10216, obtained by the Infrared Space Observatory. For this object, molecules can also be detected through their rovibrational transitions against the bright far-red, and near- and mid-infrared continuum of the star.

Rotational transitions are very characteristic for molecules and, at the high resolution allowed by heterodyne techniques, precise molecular identifications can be made using laboratory measured rotational constants. Over a 100 different molecules have been detected in interstellar space (**Table 1**) and new ones are found at a rate of a few per year. Some of these species are very simple well-known molecules such as water and ammonia; however, most are rather exotic, unsaturated carbon chain molecules, radicals and ions. To a large extent this reflects observational selection effects. The detection of these species is heavily favoured because of their large dipole moments and their relatively small partition function, which allows detection of even trace amounts. Also, while in terrestrial laboratories many of these species are very transient, they can persist much longer under the extreme vacuum conditions of the interstellar medium

when properly shielded from stellar ultraviolet photons by the ubiquitous dust grains. Many of the ions are protonated versions of stable molecules such as water and CO. Finally, isotopomers of many of these species have been discovered as well.

The intensity of rotational line emission depends on the density and temperature of the gas as well as the abundance of the molecular species. Because many lines of the rotational ladder of a species can be measured, these spectra provide excellent probes of the physical conditions of the emitting gas. Most of the molecules are present in so-called molecular clouds, which are dense for interstellar standards ($1000\ \text{molecules cm}^{-3}$), cold (10 K), large-scale (30 light years) structures. Approximately 40% of the interstellar gas is in such molecular clouds. The large column densities of dust associated with these molecular clouds shields the molecules from the dissociating radiation from surrounding bright stars and allows them to survive. At the same time, these molecules allow the clouds to cool down to low temperatures and be compressed. Gravity can then overcome the thermal and magnetic support of these clouds, and new stars can form. Molecular clouds are indeed the exclusive sites for the formation of new stars. The molecular inventory of these clouds is therefore directly fed into newly formed stars and their planetary systems.

The most abundant species in molecular clouds is H_2 , simply because hydrogen is the most abundant element. CO is second at an abundance relative to hydrogen of 10^{-4} . Most of the other species in Table 1 are trace species at abundances of 10^{-8} or less. Many processes

Figure 3 Far-infrared spectrum of the ejecta from the star IRC 10216 obtained with the Long-Wavelength Spectrometer on board the Infrared Space Observatory at a resolution of approximately 100. Most of the lines in this spectrum can be identified with pure rotational transitions in CO, HCN and their isotopomers (top arrows). Rotational transitions associated with the lowest vibrational states of HCN are also present (bottom arrows). Reproduced with permission from Cernicharo J, Barlow MJ, González-Alfonso, et al. (1996) *Astronomy and Astrophysics* 315: L201.

contribute to the formation and evolution of these molecules. Molecular hydrogen is thought to be formed on the surfaces of dust grains (mainly because gas-phase routes towards this molecule are measured to be extremely slow). Once molecular hydrogen is present, other molecules can be formed through gas-phase ion-molecule reactions. These reactions are fast and, unlike neutral-neutral reactions, often do not have reaction barriers because of the Coulomb interaction. A trace amount (10^{-7}) of ionization is provided by penetrating high-energy (MeVs) cosmic ray protons. The cosmic rays ionize H_2 producing H_2^+ , which reacts with another H_2

to form protonated molecular hydrogen, H_3^+ . This species can transfer its proton to other species, in particular atomic oxygen, to start the chain that will lead to the formation of OH, H_2O and their protonated forms. Reaction of these species with atomic C and C^+ leads then eventually to the formation of CO. This very stable molecule locks up most of the available carbon, but trace amounts of atomic C and C^+ present can drive the build up of more complex carbon molecules including the carbon chains. Finally, the low temperatures (10 K) of molecular clouds will enhance isotopic fractionation. In particular, because of the zero-point energy difference

^aSpecies denoted with * have only been detected in the circumstellar envelope of carbon-rich stars, notably IRC 10216. Most molecules have been detected at radio and millimetre wavelengths, unless otherwise indicated (IR, VIS or UV). Isotopomers of many of these species – including D, ¹³C, ¹⁵N, and ¹⁸O – have been detected as well.

between hydrogenated and deuterated molecules (typically 100–500 K), deuterium fractionation is important and the abundance of deuterated molecules can reach levels comparable to their hydrogenated counterparts, despite the very low elemental abundance of deuterium (10^{-5} relative to H).

Vibrational Spectroscopy

Ices in Star-Forming Regions

Gas and dust in molecular clouds are very cold, and hence vibrational spectroscopy is limited to absorption spectroscopy, where a newly formed star inside the cloud or a chance superposition of the cloud against a background star provides the continuum against which the spectra can be measured. Such spectra show a variety of broad absorption features due to simple molecular species: H₂O, CH₃OH, CO, CO₂, OCS and CH₄. **Figure 4**

shows as an example the 2–20 μ m spectrum of the luminous protostar W33A. These species are very volatile and are therefore never seen in emission in the infrared. At this resolution, it is easy to separate absorption due to gaseous molecules from that of solid ices (**Figure 5**). **Table 2** summarizes the observed composition of interstellar ice towards this source. H₂O dominates the column density of ice by a large factor. The carbon-bearing species, CO, CO₂ and CH₃OH, are less abundant by a factor 10–20, while CH₄ is at the 1% level compared to H₂O. This dominance of H₂O is directly evident from the complete IR spectrum of this source (**Figure 4**), since the H₂O absorption features are more conspicuous than any of the other ice features, and yet the intrinsic strength of absorption features are very similar for most molecules.

The most striking aspect of the IR spectrum of interstellar ices is the apparent simplicity of the composition. Nevertheless, this global ice inventory is somewhat misleading. The peak position and profile of

Figure 4 The 2–20 μm spectrum of the protostar W33A obtained at a spectral resolution of 250 using the Short-Wavelength Spectrometer on board the Infrared Space Observatory. Except for the 10 μm silicate band, all features are due to simple molecules in ice mantles.

absorption bands are sensitive to the molecular environment of the absorbing species in the ice. Thus, H_2O is mainly located in an H_2O -rich ice, as evidenced by the width and peak position of the 3 and 6 μm bands representing OH stretching and bending modes. While some of the solid CO is embedded in the H_2O ice, most of the absorption is due to an apolar ice component dominated by O_2 , N_2 or CO itself. Solid CO_2 studies also reveal the presence of multiple ice mantle components along many lines of sight. **Figure 6** shows the bending mode of CO_2 in the spectra of a number of protostars embedded in their natal molecular clouds. The spectra show weak structure in the depth of the band at 15.1 and 15.25 μm as well as a shoulder at approximately 15.4 μm . These spectra are well fitted by laboratory spectra of mixtures of H_2O , CH_3OH and CO_2 heated to approximately 100 K. At about that temperature, these mixtures segregate into separate H_2O , CH_3OH and CO_2 ices, and this is reflected in the absorption spectra. Thus, the features at 15.1 and 15.25 μm are due to the bending mode in pure solid CO_2 . This mode is doubly degenerate and splits when the axial symmetry of the molecule is broken in the CO_2 matrix. The observed peak positions are slightly shifted from those of a pure CO_2 ice film because, in these warmed-up mixtures, the CO_2 ice clusters are still embedded in the H_2O and CH_3OH ices. The strength of the 15.1 and 15.25 μm features in the interstellar spectra reflect the timescale of this thermal processing, that is lifetime of the newly formed star. The CO_2 stretching mode is not sensitive to these effects and neither the laboratory nor the interstellar spectra show much variation upon warm up. However, the stretching mode of the ^{13}C isotope of solid CO_2 does show these effects, and the interstellar spectra are in good agreement with the conclusions derived from the bending mode of $^{12}\text{CO}_2$.

Figure 5 Absorption spectra of a number of protostars in the stretching region of CO and CO_2 obtained by the Short-Wavelength Spectrometer on board the Infrared Space Observatory. The broad band at approximately 4.25 μm is due to the stretching mode of solid CO_2 . The narrow features in the 4.5–4.9 μm range are the rovibrational transitions of gaseous CO. The broader feature in the Q-band gap of this linear molecule is the stretching mode of solid CO. The narrow emission feature at approximately 4.66 μm in the spectrum of NGC 7538 IRS 1 is a hydrogen recombination line. These different sources are characterized by different temperatures of the absorbing gas and ices. The relative amounts of the rather-volatile molecule CO in the gas phase and the ice reflect this rather strikingly. Reproduced from van Dishoeck EF (1998) *Faraday Discussions* 109: 31, with permission of the Royal Society of Chemistry.

Interstellar ices are formed through the accretion of simple gas-phase species on surfaces of small dust grains injected into the interstellar medium by stars. Typical accretion rates are about one species a day. Interstellar grain surface chemistry is dominated by hydrogenation and oxidation reactions. Of particular interest are those reactions involving the dominant gas-phase molecule, CO, leading to H_2CO , CH_3OH and CO_2 . Atomic oxygen, carbon and nitrogen are readily hydrogenated to H_2O , NH_3 and CH_4 . In the general interstellar medium, the omnipresent stellar radiation photodesorbs these species, keeping the grain surfaces clean. However, the shielding provided by molecular clouds allows thin (tens of nanometre) ice mantles to form. During the gravitational

Table 2 Observed abundances in interstellar ices

Species	W33A	NGC 7538-IRS 9	Comets
H ₂ O	100	100	100
NH ₃	—	12	1
CH ₄	0.4	2	0.2–1.2
CH ₃ OH	4	5	0.3–5
CO	2	12	6
CO ₂	3	15	3
OCS	0.04	—	0.1
HCOOH	3	3	0.2

Observed abundances normalized to that of water ice (= 100). W33A and NGC 7538-IRS 9 are two luminous protostars which span the observed range in interstellar ice composition. The abundances for the comets are an average of those observed for comets Hyakutake and Hale-Bopp.

collapse associated with the formation of a new star, the accretion rate of gas-phase species on a grain becomes so high that essentially all species can freeze out in these ice mantles. Such ice grains entering the cold outskirts of protoplanetary disks can survive and agglomerate into large bodies, leading to the formation of comets. The great similarity in molecular inventory and abundances of interstellar ices and comets (cf. **Table 2**) supports such a scenario. Besides grain surface chemistry, the composition of interstellar ices is also affected by thermal processing when the ices are too close to a newborn star, much like the outgassing of comets when they approach the inner solar system. The difference in volatility between apolar molecules, such as CO and CH₄, and hydrogen-bonding species, such as H₂O and CH₃OH, can then lead to thermal fractionation.

Interstellar and Circumstellar PAHs

Ground-based, airborne and space-borne observations have shown that the IR spectra of bright sources with associated dust and gas are dominated by relatively broad emission features at 3.3, 6.2, 7.7, 8.6 and 11.3 μm , which always appear together. Because the carriers of these bands remained unidentified for almost a decade, these bands have become collectively known as the unidentified infrared (UIR) bands. These bands are now unequivocally identified with an aromatic carrier, and this name is somewhat of a misnomer. Nevertheless, the abbreviation has stuck and is still widely used. As an example, **Figure 7** shows three mid-infrared spectra of carbon-rich outflows from stars in the latest stages of their evolution. It is now known that these emission features are not limited to stellar outflows but are also present in the spectra of disks of newly formed stars, the spectra of the surfaces of interstellar gas clouds, the spectra of reflection nebulae, the spectra of ionized nebulae around massive stars, and the spectra of the general interstellar medium of the Milky Way and other

Figure 6 Absorption spectra of the bending mode of CO₂ ice towards a number of protostars embedded in their natal molecular clouds obtained by the Short-Wavelength Spectrometer on board the Infrared Space Observatory at a spectral resolution of approximately 2000. The observed profiles show weak features at approximately 15.1 and 15.25 μm as well as a shoulder at approximately 15.4 μm . The solid lines are laboratory spectra of the H₂O:CH₃OH:CO₂ = 1:1:1 mixture deposited at 10 K and then warmed to temperatures in the range of 114–118 K. The sharp structure near 14.97 μm in some sources is due to the rovibrational transitions in the Q branch of gaseous CO₂, which at this resolution pile up in one spectral resolution element. The individual P and R branch lines are too weak to be observable at this resolution.

nearby galaxies. The carrier is thus ubiquitous and able to withstand the harsh environment of interstellar space.

These bands are very characteristic for aromatic hydrocarbon species in which carbon atoms are arranged in hexagons decorated by hydrogens at the edges. These features are observed far from illuminating sources where interstellar gases are cold (10–100 K) and exciting collisions infrequent (once a day). The emission is therefore attributed to infrared fluorescence from a collection of vibrationally excited PAH species electronically pumped through the absorption of one stellar UV photon (about 10 eV). During the vibrational cascade (approximately 1 s), the molecule emits in its C–H and C–C vibrational modes

Figure 7 The 3–15 μm emission spectra of three stars in the latest stages of their evolution illustrating the ubiquitous nature and the richness of the UIR spectrum. These spectra were obtained with the Short-Wavelength Spectrometer on board the Infrared Space Observatory at a spectral resolution ranging from 250 to 2000.

(the UIR bands) and, afterwards, the molecule remains cold (approximately 10 K) until the next UV photon is absorbed (about a day). Analysis of this process leads then to a determination of the size of the emitting species of approximately 50 carbon atoms. Thus, the carriers of the UIR bands are PAH molecules such as hexabenzocoronene ($\text{C}_{48}\text{H}_{24}$) and circumcoronene ($\text{C}_{54}\text{H}_{18}$).

Typical abundances of PAHs are of the order of 10^{-7} relative to hydrogen, which makes these species the most abundant polyatomic molecules present in space. Vibrational spectroscopy is eminently suited for detecting the presence of classes of molecules, but it is much more difficult to identify specific molecules within a collection of species. However, while the gross characteristics of these stellar and interstellar spectra are very similar, when examined in detail, they vary from source to source. Analysis of these variations may well provide us with a tool to identify specific molecules within the circumstellar and interstellar PAH family, and such efforts, supported by extensive laboratory studies, are now underway.

The 11–15 μm region of the spectrum is rich in details showing bands at 11.0, 11.3, 11.9, 12.8, 13.6, 14.2 and 14.8 μm plus a number of weaker shoulders (**Figure 8**). Emission features in this spectral region are due to a C–H out-of-plane deformation mode of aromatic

hydrocarbons and the observed pattern is very characteristic for the edge structure of the emitting aromatic species. Owing to coupling between the vibrating H atoms, the exact peak position of these modes depends on the number of directly adjacent H atoms (i.e. bonded to neighbouring C atoms on a ring). The 11.3 μm band is attributed to this mode for isolated Hs in PAHs, while the 11.9 and 12.8 μm bands arise from 2 and 3 adjacent Hs. The weak bands at 13.6 and 14.2 μm are likely due to phenyl (5 s) groups; that is one ring connected by a single bond to the rest of the PAH. In that case, the 14.2 μm band is actually a ring-bending mode.

These PAHs are thought to form in carbon-rich stellar winds through chemical processes akin to those occurring in sooting flames and other terrestrial combustion environments. Acetylene is the precursor molecule from which larger species, and eventually soot, are formed. This process starts with the formation of the first aromatic ring (e.g. benzene). Rapid chemical growth of this ring through the addition of acetylene then forms larger PAHs. Further chemical growth as well as clustering of these PAHs leads to the formation of small (≈ 100 nm) soot particles. These soot particles and the gas are driven out by the radiation pressure of the luminous star, thereby enriching the interstellar medium.

Figure 8 The 10–15 μm spectrum of the outflow from a star known as the Red Rectangle because of the rectangular appearance of its associated reflection nebula on red plates. Bands in this spectral region are largely due to the C–H out-of-plane bending mode whose exact peak position is sensitive to the number of adjacent H atoms involved. The boxes underneath the spectra give the ranges where PAHs with the indicated number of adjacent H atoms emit. The arrow labelled 6 indicates the position for benzene. These spectra were obtained with the Short-Wavelength Spectrometer on board the Infrared Space Observatory at a spectral resolution ranging from 250 to 2000.

Electronic Spectroscopy

Elemental Abundances in the Galaxy

With a few notable exceptions, most atomic species possess strong absorption lines at far-ultraviolet wavelengths and their detection requires space-borne instrumentation. Since the 1970s, a number of missions have measured electronic absorptions of many elements as well as a few diatomic molecules. These lines are due to gas in the interstellar medium measured in absorption against a bright background star. A sample of such is shown in **Figure 9** obtained by the Goddard High-Resolution Spectrograph on the Hubble Space Telescope. At the high spectral resolution of this instrument, these absorption lines show components due to many individual clouds along the line of sight, which have different velocities with respect to the Sun because of galactic rotation. The lines shown cover a range of line strengths, due to differences in intrinsic oscillator strength and column density of the absorbing species involved. These observations allow the determination of the abundance of elements in the interstellar medium with respect to atomic hydrogen. Typically, the measured abundances fall short of the elemental abundances measured in the Sun, in solar system objects such as

meteorites, and in stellar photospheres (**Figure 10**). Because the Sun and other stars are formed from interstellar gas and, hence, should have very similar abundances, these large differences are attributed to the depletion of these elements from the gas phase in the form of small solid dust grains. This is supported by the loose correlation of the amount of material depleted from the gas phase with condensation temperature of the likely condensate of these elements (**Figure 10**). These dust grains are formed in the high-density, high-temperature environments of stars and injected into the interstellar medium in a supernova explosion or a stellar wind.

The Diffuse Interstellar Bands

The diffuse interstellar bands (DIBs) are weak absorption features, which typically appear in the visual range of stellar spectra. These bands were discovered over 60 years ago, and their origin in interstellar material along the line of sight towards these stars was quickly established, because they do not share the stellar velocity variations in spectroscopic binaries and their strength increases with distance and the column of absorbing interstellar material along the line of sight. **Figure 11** shows a compilation of these absorption features. The richness of the DIB spectrum is apparent: over 300 DIBs have been discovered. Most DIBs have a width in the range 0.5–3 $\text{\AA}$, but bands as broad as 20 $\text{\AA}$ exist as well. The strengths of individual DIBs correlate reasonably well with each other but not perfectly, indicating that more than one carrier is involved. Some DIBs show substructure at high spectral resolution (**Figure 12**). In recent years, a few DIBs have been observed in the ultraviolet and far-ultraviolet part of the spectrum. But such studies are severely hampered by atmospheric absorption and by interstellar absorption due to solid dust grains in the interstellar medium, which increases rapidly with increasing frequency.

At present, none of the DIBs has been identified with certainty – not for lack of trying, though. The DIBs are too broad to be due to electronic transitions in atoms. For decades, the DIBs were thought to be associated with small (100 nm) dust grains which are responsible for the reddening and extinction of starlight. In that view, the DIBs were just thought to represent a small substructure in the extinction properties of the grains likely due to electronic transitions in impurities in an otherwise dielectric material such as silicates or oxides. However, the constant peak position and width of the DIBs in all directions argue against that since, theoretically, the profile is expected to be very sensitive to the grain size as well as the detailed composition of the matrix material. Also, these interstellar dust grains are observed to cause a small amount of polarization of starlight but the DIBs are unpolarized.

Figure 9 Normalized intensity versus heliocentric velocity for a number of lines of different interstellar atoms towards the star HD 93521. These were obtained with the Goddard High-Resolution Spectrograph on the Hubble Space Telescope at a resolution of approximately 100 000. Tick marks at the top and bottom of the panels indicate individual absorption components present along the line of sight to this star.

Figure 10 Gas-phase abundances measured towards the star z Oph of various elements relative to atomic hydrogen (X/H) and normalized with respect to solar abundances (X/H)₀ plotted versus condensation temperature of these elements. The condensation temperature is the temperature at which 50% of that element is depleted from the gas phase into the solid phase. The error bars on the squares indicate measurement errors only. Representative uncertainties in the solar abundances, oscillator strength and condensation temperature are indicated in the lower left-hand corner.

Figure 11 A compilation of the diffuse interstellar bands spectrum. Individual DIBs have been smoothed to a spectral resolution of 2 Å, and their strength normalized to a column corresponding to line-of-sight dust reddening equal to unity. Reproduced with permission from Jenniskens P and Désert F-X (1994). *Astronomy and Astrophysics Supplement Series* 106: 39.

Instead, it is now generally accepted that the DIBs are due to absorption by interstellar gaseous molecules. Absorption by molecules (CH, CN) in the visible part of the spectrum was detected only shortly after the discovery of

Figure 12 Line profile for the 16 613 Å DIB at a resolution of about 100 000 revealing a three-peaked structure characteristic for rotational contours of electronic transitions in molecular species. Reproduced with permission from Ehrenfreund P and Foing B (1996) *Astronomy and Astrophysics* 307: L25

the DIBs, but these species are too small and have too low an abundance to be responsible for the DIBs. This and the perceived difficulty to form an abundant concentration of molecules in the harsh environment of the interstellar medium has long driven the field away from a molecular carrier. However, presently, there is abundant evidence from other wavelength regions for the presence of large and complex molecules such as PAHs in the interstellar medium, and this argument has lost much of its persuasion. There is also direct observational support for a molecular origin of the DIBs. One of the key pieces of evidence for this was found in the visible spectrum of the red rectangle. The spectra of the nebulosity associated with this object (known to be bright in PAH emission features in the infrared) show emission features near the wavelengths of prominent DIBs, including those at 5797 and 6613 Å, and, with increasing distance from the central illuminating star, their peak position shifts closer and closer to that of the interstellar DIB absorption features. These visual emission bands also become progressively narrower with distance from the star. This is the behaviour expected for fluorescence of electronic transitions in molecules excited by the radiation of the central star. The

gas flowing away from the star cools, and, consequently, fluorescence is dominated by lower and lower rotational lines. In the cold interstellar medium, absorption occurs only from the lowest rotational levels. A molecular origin is also supported by the substructure observed at high resolution in some DIBs, which is characteristic for rotational contours of electronic transitions in molecules (cf. **Figure 12**). Analysis of these line profiles shows that, depending on the class of species responsible (i.e. the rotational constants of the electronic states involved), the carrier contains between 10 and 60 C atoms. Finally, two DIBs have been detected in the far-red (9577 and 9632 Å), which are close to laboratory measured absorption features of the fullerene cation, C_{60}^+ , in a neon matrix.

The carrier of the DIBs has still not been identified unequivocally. Part of this is, likely, that there is not one molecular carrier, or even one class of molecular carriers, responsible for all the DIBs, but rather a variety of species contribute. Among the likely candidates are PAHs, fullerenes and carbon chains (such as C_7). Vigorous studies on the visible absorption properties of such species are underway at various laboratories. Recently, a new mechanism for the DIBs has been proposed involving double excitation of atoms in Rydberg matter, calculations of which show a strong agreement with many observed DIBs.

Introduction

In vivo magnetic resonance spectroscopy (MRS) aims at noninvasive determination of tissue concentrations of various metabolites and compounds in animals or humans.

It therefore enables metabolism to be investigated *in vivo*, and pathological as well as drug- or exercise-induced changes of the metabolism to be detected. *In vivo* MRS is based on not only protons (^1H) but also phosphorus (^{31}P) or carbon (^{13}C) nuclei. Animal and human MRS studies exploiting all three nuclei have improved the understanding of basic physiological processes and have shed light on the pathophysiology of diverse disorders. Owing to its high sensitivity and hence possible spatial specificity, along with the fact that it can be recorded using the same RF coil as used for routine clinical magnetic resonance imaging, especially *in vivo* ^1H MRS is also rated as a promising tool for clinical diagnostics.

Visible Metabolites

Approximately 26 metabolites reach tissue concentrations that allow for their detection and quantification by *in vivo* ^1H MRS – among them neurotransmitters and markers for energy metabolism, cell growth/death, and inflammation. The highest number of metabolites can be detected in brain tissue: N-acetyl-aspartate (NAA), N-acetyl-aspartyl-glutamate (NAAG), choline-containing compounds (Cho), total creatine (tCr), myo-inositol (ml), scyllo-inositol (scylloI), glutamate (Glu), glutamine (Gln), gamma-aminobutyric acid (GABA), glucose (Glc), acetate (Ace), aspartate (Asp), glutathione (GSH), lactate (Lac), alanine (Ala), taurine (Tau), ascorbic acid (Asc), glycine (Gly), lipids (Lip), phosphorylethanolamine (PE), and broad resonances from macromolecules (MMs) and amino acids (AAs). Very specific information about insulin sensitivity can be extracted from detectable intramyocellular lipid (IMCL) and extramyocellular lipid (EMCL) in muscle tissue, where trimethylamine (TMA), total creatine, carnosine (Car), and taurine also can be quantified. Inside the prostate gland citrate (Cit), choline, creatine, and spermine (Spe) reach sufficient concentrations. In general, choline concentrations can be used as a cancer marker throughout the entire body, for example, in breast, liver, or bones. However, primarily due to spectral overlap not all of the mentioned metabolites can be distinguished at low field strength without using editing or 2D resolved spectroscopy methods, whereas at a field strength of 7 T or higher most of them can be quantified based on simple 1D *in vivo* ^1H MRS. The following sections give an overview of the most important metabolites, their appearance in the spectrum, and their role in metabolism.

N-Acetyl-aspartate (NAA)

The concentration of NAA in the nervous system is 6–12 mM. The most prominent singlet in a ^1H brain spectrum stems from the CH_3 group and occurs at 2.02 ppm; in addition, multiplets from strongly (2.69 and 2.49 ppm; CH_2 group) and weakly (4.39 ppm; CH group) coupled spin systems are visible. NAA is a neuronal marker; thus its concentration correlates with neuronal density and neuronal function. Its role is poorly understood – hypotheses include osmoregulation, a breakdown product of NAAG, acetyl storage for fatty acid, and myelin synthesis. NAA decrease is observed in tumor, stroke, multiple sclerosis, epilepsy, hyp-/anoxia, inflammation, dementia, and trauma, whereas it increases during brain development and maturation as well as in Canavan's disease (aspartoacylase deficiency).

N-Acetyl-aspartyl-glutamate (NAAG)

The concentration of NAAG in the nervous system is 0.6–3 mM. A singlet at 2.04 ppm (CH_3 acetyl moiety) can be distinguished from NAA at field strengths of 7T or higher; in addition, a multiplet pattern from a strongly coupled spin system is visible between 1.8 and 2.7 ppm as well as a doublet of doublets from a weakly coupled spin system, which is centered at 4.6 ppm. NAAG is a peptide neurotransmitter and possibly glutamate storage form.

Creatine and Phosphocreatine (tCr = Cr + PCr)

These amount to a total concentration of ~ 6 –12 mM in brain and muscle; two prominent singlets are found at 3.03 ppm (CH_3) and 3.93 ppm (CH_2). Total Cr serves as energy buffer ($\text{H} + \text{PCr} + \text{ADP} \rightleftharpoons \text{ATP} + \text{Cr}$) and energy shuttle to transport energy from mitochondria to energy-utilizing sites. The total Cr concentration stays constant during exercise; hence, Cr is often used as internal reference peak for relative quantification. Total Cr decreases in acute and subacute stroke, brain tumors, brain metastasis, abscesses, and inborn errors of the creatine synthesis system.

Choline-Containing Compounds (Cho)

The concentration of Cho is 2 mM in the brain, but it occurs throughout the body. In the brain, choline, phosphorylcholine, and glycerophosphorylcholine contribute to the singlet at 3.22 ppm (CH_3) and multiplets at 3.54 and 4.05 ppm (CH_2), whereas there is no contribution from acetylcholine. In muscle, other TMA-containing compounds especially betaine/trimethylglycine, a methyl group donor, contribute to the singlet at 3.22 ppm. Cho is involved in pathways of phospholipid synthesis and degradation, and thus reflects membrane synthesis and degradation. Cho increases in brain tumors, any

cancer, demyelinating plaques, stroke, inflammation, and degenerative white matter diseases.

Myo-inositol (mI)

The concentration of mI in the brain is 4–8 mM; the inositol ring protons give rise to multiplets at 3.60 ppm (H_6, H_4), 3.54 ppm (H_1, H_3), 3.28 ppm (H_5), and 4.05 ppm (H_2). It is an astrocyte/glia marker, a second messenger, and an osmoregulator. mI increases in Alzheimer's disease, renal failure, diabetes mellitus, and hyperosmolar states and decreases in abscesses, hepatic encephalopathy, tumors, and stroke.

Lactate (Lac)

The concentration of Lac in a healthy brain is 1 mM, and up to 20 mM in brain lesions and exercising muscle. Its NMR spectrum shows a weakly coupled spin system with a doublet at 1.33 ppm (CH_3 , upright at short $T_E = 288$ ms, inverted at $T_E = 144$ ms) and a quartet at 4.11 ppm (CH, often suppressed with water suppression). To distinguish it from lipids it is mostly detected at long echo times. It is an end product of anaerobic glycolysis; its accumulation is a sign of impaired energy metabolism or impaired oxygen delivery. Lac increases in stroke, an-/hypoxia, mitochondrial diseases, tumors (brain and metastases), epileptic discharges, and abscesses/infections, as well as during neuronal activation.

Glutathione (GSH)

The concentration of GSH in brain tissue is approximately 1–3 mM. Multiple multiplets are found at 2.15/2.16 ppm ($^4\text{CH}_2$), 2.51/2.56 ppm ($^3\text{CH}_2$), 2.92/2.97 ppm ($^7\text{CH}_2$), 3.77 ppm (^2CH and $^{10}\text{CH}_2$), and 4.56 ppm (^7CH). GSH is primarily found in astrocytes and is thought to be an antioxidant and involved in AA transport and cysteine storage. Owing to heavy spectral overlap its concentrations can only be assessed based on editing or 2D resolved spectroscopy methods at low field strength or by conventional 1D ^1H MRS at ultra-high field (from 7 T upwards). Altered GSH levels were reported in Parkinson's disease, schizophrenia, and neurodegenerative disorders.

Glutamate (Glu)

The concentration of Glu in brain tissue is 6–12 mM. Multiple multiplets are found at 2.05 ppm ($^\beta\text{H}$), 2.12 ppm ($^\beta\text{H}$), 2.34 ppm ($^\gamma\text{H}$), and 3.75 ppm ($^\alpha\text{H}$). Glu can be found in astroglia and neurons and is a major excitatory neurotransmitter. It is also in fast exchange with TCA cycle intermediates and as an AA involved in protein biosynthesis. Using conventional 1D *in vivo* ^1H MRS,

resonance lines of glutamate and glutamine cannot be distinguished at low field strength due to their very similar chemical structures. This is, however, possible at field strength of 7T or higher or alternatively with editing or 2D -resolved spectroscopy methods at lower field strength. The total Glu + Gln concentration (Glx) increases in stroke, hyp-/anoxia, epilepsy, neurodegenerative diseases (e.g., ALS), and hepatic encephalopathy. In addition, changes of Glu concentrations were reported for psychiatric disorders such as major depression, bipolar disorder, or schizophrenia.

Glutamine (Gln)

The concentration of Gln in brain tissue is 2 mM. Multiple multiplets are formed at 2.11 ppm ($^{\beta'}\text{H}$), 2.13 ppm ($^{\beta}\text{H}$), 2.44 ppm ($^{\gamma}\text{H}$), and 3.76 ppm ($^{\alpha}\text{H}$). Gln can be found in astroglia and neurons and is a precursor of the neurotransmitters Glu and GABA; it is also an AA and hence involved in protein biosynthesis. In addition to the changes described for Glx, Gln concentrations possibly decrease in certain cortical areas in major depression.

Gamma-aminobutyric acid (GABA)

The concentration of GABA in brain tissue is approximately 1 mM. Three multiplets are formed at 1.89 ppm ($^2\text{CH}_2$), 2.28 ppm ($^1\text{CH}_2$), and 3.01 ppm ($^3\text{CH}_2$). GABA is a major inhibitory neurotransmitter. GABA concentrations can be assessed based on editing or 2D resolved spectroscopy methods at low field strength or by 1D MRS at ultra-high-field strength (from 7T). Altered GABA concentrations were reported for psychiatric disorders such as major depression and schizophrenia, neurological disorders, epilepsy, and alcohol/drug abuse.

Glucose (Glc)

The concentration of glucose throughout the human body is 1–2 mM; two anomers (alpha: 36%; beta: 64%) exist. Two broad lines centered at around 3.43 and 3.80 ppm originate from complex multiplet pattern due to a strongly coupled spin system ($^2\text{CH}-^5\text{CH}$, $^6\text{CH}_2$); in addition, a doublet from a weakly coupled spin system occurs at either 4.63 ppm (^1CH – beta anomer) or 5.22 ppm (^1CH – alpha anomer). Glucose is the major energy source in animals and humans and precursor of a large number of compounds. Even at high field strength it is difficult to reliably quantify glucose based on conventional 1D ^1H MRS, which is slightly improved by 2D resolved MRS approaches. An alternative is ^{13}C MRS after injection of ^{13}C -labeled glucose. Glucose concentrations change during exercise or neuronal activation as well as in various diseases that have an impact on the energy metabolism.

Taurine (Tau)

Taurine concentrations amount to approximately 1.5 mM in brain tissue and 2–6 mM in muscle tissue. Two triplets from two adjacent methylene groups occur at 3.25 and 3.42 ppm. At low field strength taurine resonances completely overlap with mI and Cho. Thus, for unambiguous Tau quantification, either editing or 2D resolved spectroscopy methods or a field strength of 7T or higher is necessary. The exact function of taurine is poorly understood, but osmoregulation, modulation of neurotransmitter action, adipose tissue regulation, and membrane stabilization have been suggested. Tissue taurine levels decrease with age and depend on diet.

Acetate (Ace)

Acetate concentrations amount to 0–0.5 mM in healthy brain tissue. One singlet at 1.9 ppm originates from the only methyl group. Acetate is in exchange with TCA cycle intermediates and is almost exclusively metabolized inside astroglia. Although Ace is usually not observed in healthy brain tissue, its concentration can rise substantially in brain abscesses.

Alanine (Ala)

Alanine concentrations amount to 0.5 mM in the healthy brain. It has a weakly coupled spin system with a doublet at 1.47 ppm (CH_3) and a quartet at 3.78 ppm (CH). Alanine is an AA; it is also in exchange with TCA cycle intermediates and plays an important role in gluconeogenesis in the liver. Ala can be detected at long echo times or with spectral editing methods to distinguish it from MMs and Lip. Ala concentrations increase to detectable levels in abscesses, meningiomas, and high-grade tumors.

Phenylalanine (Phe)

This has a concentration of up to 0.5 mM in healthy brain tissue and up to 5 mM in phenylketonuria (PKU). The phenyl ring protons give rise to a complex strongly coupled multiplet between 7.30 and 7.45 ppm, which is observed as one broad resonance *in vivo* and used for phenylalanine detection; further three doublets of doublets from the aliphatic protons occur at 3.11, 3.27, and 3.98 ppm.

Macromolecules (MMs)/Amino Acids (AAs)

The macromolecular baseline in brain tissue consists of 10 distinct broad resonance lines between 0.9 and 4.3 ppm, which were partly assigned to certain AAs possibly bound to small peptides. Distinct AA resonances show a substantial increase in abscesses, stroke, and tumors.

IMCL/EMCL

Lipid from subcutaneous or interstitial adipose tissue and bone marrow, which is referred to as EMCL, can be readily observed throughout the body and gives rise to several resonance lines between 0.9 and 6 ppm, with the most prominent ones being at around 1.5 ppm. In contrast, lipid from phospholipids in cell membranes can usually not be observed due to its immobility. Thus, lipid accumulation in brain tissue is a sign for necrosis if a contribution from skull lipid can be excluded. In muscle tissue, IMCL can be distinguished from EMCL due to differences in the bulk magnetic susceptibility shift. IMCL is stored inside liposomes, lipid droplets in the cytoplasm, next to mitochondria inside cells. In diabetes, IMCL levels inversely correlate with insulin sensitivity, otherwise IMCL levels depend on physical exercise and diet.

Citric Acid (Cit)

Citrate has a concentration of up to 60 mM in the prostate gland; at physiological pH and cation concentrations a strongly coupled AB spin pattern centered around 2.57 and 2.72 ppm is observed at physiological pH and cation concentrations. The exact appearance and phase of the citric acid resonances is a nonperiodic function of echo time and field strength. Citric acid is a TCA cycle intermediate and does not usually accumulate. Inside prostatic tissue high zinc levels inhibit its oxidation. Citrate levels drop in malignant adenocarcinoma due to largely reduced zinc levels.

Applications: Clinical Diagnostics

Today ^1H MRS allows the noninvasive detection of characteristic metabolic changes in many diseases. However, it still has not been established as a routine tool for clinical diagnostics. The reasons for this are insufficient signal-noise ratio (SNR), spectral information content, and spatial resolution at standard field strength of clinical MR scanners (0.5–1.5 T). The recent introduction of high (3 T) and ultra-high field (7 T) MR scanners for humans allowed for a substantial increase in SNR and the number of detectable and quantifiable metabolites, which opens up completely new perspectives for the future of ^1H MRS in the clinical environment. Additional problems are artifacts introduced by flow, motion, and susceptibility differences that restrict the application of clinical ^1H MRS to very few organs. Other limiting factors are acquisition speed, organ coverage, and the lack of reliable and easy-to-apply methods for the estimation of metabolite concentrations in millimolar (absolute quantification) – especially in diseases and for magnetic resonance spectroscopic

imaging (MRSI). Methods development groups have already overcome quite a few of these additional limitations and introduced accelerated MRSI, ECG triggering, respiratory gating, volume tracking, improved shimming algorithms, and novel reference standards for absolute quantification. However, not all of these techniques have been incorporated into commercial scanner software packages yet. In addition, acquisition and interpretation of *in vivo* ^1H MR spectra require a lot of experience, since artifacts have to be recognized as such and not mistaken as real metabolite signal and the biochemistry behind metabolic changes has to be understood. Another problem is that individual metabolite concentrations and hence the spectral pattern changes throughout one organ and with age. Hence a database that shows typical spectra from different regions of brain, prostate, liver, muscle, etc., at different ages and characteristic changes for the most common diseases for different regions and ages is needed, but is still missing.

Brain

The major clinical application of ^1H MRS is differential diagnostics of different lesions in the human brain (**Figure 1**). Tumors can be distinguished from multiple sclerosis plaques, abscesses, or lesions caused by cerebral infarction. Furthermore, tumor grading is possible; for example, a meningioma can be distinguished from a low-grade ependymoma and a high-grade glioblastoma. Tumor recurrence and hence therapy response can be monitored by determining the tissue Cho concentrations. In the case of cerebral infarction or other forms of hypoxia, lactate and NAA levels in the different parts of the lesions can help to predict the outcome of the patient. ^1H MRS can also be used to monitor treatment response during the acute phase of cerebral stroke. Clinical ^1H MRS can also help to find the epileptic focus in epilepsy, give complementary information in the case of brain infections, and reveal certain kinds of neurodegenerative disorders such as Alzheimer's disease. Another important group of applications are inborn genetic defects such as PKU (phenylalanine hydroxylase deficiency), Canavans disease (aspartoacylase deficiency), guanidinoacetate methyltransferase (GAMT) deficiency, X-linked adrenoleukodystrophy (Acyl-CoA synthetase deficiency), or mitochondrial cytopathies (different failures, e.g., of the electron transport chain). In these cases, ^1H MRS enables an early diagnosis, for example, in infants, since it detects the biochemical dysfunction long before cell death and organ failure, which would finally be recognized by MRI or CT. This might improve the patient outcome substantially, since therapy such as application of the missing enzymes or special diets can start as early as possible and its success can even be monitored.

Figure 1 Clinical application of *in vivo* ^1H MRS. All single-voxel patient spectra were acquired with PRESS localization using an echo time T_E of 144 ms at 1.5 T. Spectra (a) and (b) show the comparison of healthy gray matter in the occipital lobe with a traumatic lesion on the contralateral side. Neuronal injury is indicated by the missing NAA resonance and elevated Cho and Lac. Spectrum (c) stems from a glioblastoma in the mid brain just underneath the corpus callosum. Characteristic changes that mark malignancy are largely elevated Cho and Lac along with largely decreased Cr and NAA.

For focal brain lesions or inherent metabolic diseases, single-voxel ^1H MRS is the more appropriate choice (see **Figure 1**, *In Vivo* ^1H MRS Methods). It has the advantage that the spatial specificity is good, acquisition times are shorter, and quantification is more reliable than that for ^1H MRSI. For inhomogeneous lesions or also to compare healthy-appearing tissue to tissue that shows contrast changes in MRI, information about the spatial distribution of different metabolites becomes important. For these applications rather ^1H MRSI is used (see **Figure 2**, *In Vivo* ^1H MRS Methods). However, due to the effect of the point spread function, metabolite maps will just correspond to the anatomical reference if reasonably high spatial resolutions are chosen, which prolongs scan times and decreases SNR. For accelerated MRSI methods, which can achieve scan times that are more feasible to include into a clinical protocol, reliable quantification has still to be proven.

Although the *in vivo* ^1H MRS methodology has been substantially developed, the application to clinical diagnostics is so far still limited to a few brain metabolites especially NAA, Cho, Cr, Lac, mI, Glx, Lip, and MMs (**Figures 1** and **2**). Thinking of the number of possible brain diseases there are still too many ambiguities and mostly a diagnosis cannot be based on ^1H MRS alone. MRS gives rather complementary information about the metabolism that can narrow the range of possible

diagnoses. The specificity of ^1H MRS would improve if a more comprehensive neurochemical profile could be easily acquired as is possible at ultra-high field strength, and quantified in means of millimolar concentration. However, characteristic changes of all these additional metabolites are not known for most diseases and need to be investigated.

Prostate

The second important clinical application of ^1H MRS is detection of prostate cancer and distinguishing it from benign prostatic hyperplasia. To that end, citric acid and choline levels are monitored (**Figure 3**). The signal amplitude of the citric acid resonance in healthy peripheral prostate tissue is typically higher than the Cho and Cr resonances, which show almost equal intensities. In malignant adenocarcinomas, Cho shows an increase and citric acid a decrease in intensity. However, care has to be taken before putting a final diagnosis since metabolite concentrations in the healthy central prostate gland are similar to those in cancerous peripheral prostate tissue, which is the origin of most malignant adenocarcinomas. The needed spatial specificity can be provided by medium- to high-resolution multislice or 3D ^1H MRSI or single-voxel ^1H MRS from small voxels in peripheral tissue, where positions might

Figure 2 *In vivo* ^1H MRSI examination of a patient with a *Streptococcus varians* infection of the brain ($T_E = 144$ ms; PRESS MRSI; 1.5 T). The PRESS volume is indicated in yellow, whereas the FOV covered by phase encoding is shown as red grid. The infection introduced an inhomogeneous pattern of pathological conditions indicated by elevated Lac and Cho and decreased NAA and Cr. Metabolite maps reflect this metabolite distribution.

be chosen based on diffusion-weighted or postcontrast MR images.

Breast and Body

An elevated choline peak is a general cancer marker throughout the entire body.

Major applications after brain and prostate are breast cancer, liver cancer, and bone cancer. Also the application of ^1H MRS to pancreas cancer or salivary gland cancer has been reported. Depending on the organ of interest and size and homogeneity of the lesion, either single-voxel MRS or MRSI might be performed.

Forensic Medicine

Nowadays ^1H MRS is also a valuable tool for forensic medicine. Early-stage tissue degradation can be monitored precisely. Concentrations of metabolites that are usually detected *in vivo* slowly decrease over several days, whereas concentrations of metabolites such as acetate, alanine, butyrate, free TMA, or propionate that indicate putrefaction slowly increase. Once the course of time of these metabolite concentrations in certain human organs such as the brain is determined, ^1H MRS can reliably predict the postmortem interval between 5 h and 10 days after the person's death. This is apparently exactly the

time frame that can be poorly assessed by conventional forensic methods.

Applications: Physiological Research in Animals and Humans

Today ^1H MRS is in widespread use as a research tool in humans (0.5–7 T) and animals (3–16.7 T). It can help to answer diverse questions regarding fundamental physiological processes, pathophysiology of diseases, as well as the influence of drugs or other forms of treatment/invasion on the metabolism.

Functional single-voxel ^1H MRS enables the observation of metabolic changes induced by a stimulus over time. This approach helped to improve the basic understanding of energy metabolism in the healthy brain. The pathophysiology of most psychiatric and some neurological disorders such as major depressive disorder, schizophrenia, migraine, or other chronic headaches is poorly understood. Since ^1H MRS offers the possibility to measure neurotransmitter concentrations along with metabolites involved in energy metabolism or membrane synthesis and inflammatory markers with high spatial specificity, it can reveal metabolic alterations that help to understand the underlying pathophysiological

Figure 3 *In vivo* ^1H MRS outside the brain. The top row shows a typical spectrum from the human calf muscle (anterior tibialis), which was acquired using STEAM ($T_E = 18$ ms) at 7 T. Bulk magnetic susceptibility differences allow distinction between IMCL and EMCL. In addition, the fiber structure of the muscle hinders molecules from tumbling freely. The resulting orientation preference leads to splitting of the Cr (3.9 ppm) and Tau resonance lines due to residual dipolar coupling. The bottom row shows a spectrum from a healthy human prostrate recorded with a surface coil using PRESS with an echo time of 140 ms at 3 T. The appearance of the citrate resonance is a nonperiodic function of echo time and field strength.

processes. Another example is muscle ^1H MRS in diabetes (**Figure 3**). It was demonstrated that IMCL muscle concentrations correlate with insulin sensitivity. Hence *in vivo* ^1H MRS can be used to monitor the treatment response and can thus support the development of new drugs or physical training as a therapy form for diabetes patients. Another type of research are preclinical studies aiming at characterizing typical changes in spectral patterns for certain diseases and thus establishing and further developing ^1H MRS-based diagnostics. Examples are disorders that are hardly accessible by other diagnostic tools such as many brain lesions. In humans, methodological development also aims at accessing more organs of interest, such as the spinal cord or the myocardium, by ^1H MRS.

Physiological studies can be in general performed either in animals such as rats, mice, or monkeys or also directly in humans, since *in vivo* ^1H MRS is noninvasive. Animal studies have the advantage of higher external magnetic field strengths being available and thus a higher number of quantifiable metabolites. The lower magnetic field strength of clinical MR scanners might partly be

compensated for by using spectral editing or 2D resolved spectroscopy methods. Recently, 7 T research magnets for human MRI were also introduced. Safety regulations are less strict in animals and the dimensions of the investigated animals are usually smaller than a human body – both effects increase the maximal available RF power or gradient performance in related animal MR scanners substantially. Especially at high field strength related restrictions in human MR scanners might cause major scan time prolongations, signal loss due to increase in the minimal echo time or artefacts, for example, related to chemical shift displacement. Furthermore, invasive methods such as genetic alteration of the animal model, incorporation of tumor cells or infections, or administration of nonaccredited drugs to specifically enhance or block specific enzymes can be combined with ^1H MRS to test metabolic hypotheses only in animals. However, most exercise and task related studies are rather applicable in humans. Whereas animals are usually anesthetized and may stay much longer in the magnet than a human volunteer or patient ever could, which allows for more comprehensive study protocols. Disadvantages of animal studies are the divergent metabolism and anatomy of animals and humans, the difficulty to develop a realistic animal model for certain disorders, and the small size of rats and mice that require very high spatial resolution and hence lead to SNR problems. For a comprehensive understanding of a specific physiological process or the pathophysiology and treatment response in the case of a specific disease, it is most likely necessary to combine animal and human *in vivo* ^1H MRS studies. Basic pathological changes of the metabolism in certain disorders can be only reliably specified in a human ^1H MRS study but a derived hypothesis might be verified by a ^1H MRS study in a corresponding animal model. In addition, ^1H MRS should be combined with complementary methods such as *in vivo* ^{13}C and ^{31}P MRS, different MR imaging modalities, for example, functional magnetic resonance imaging (fMRI), perfusion or diffusion weighted imaging, *ex vivo* NMR spectroscopy of tissue extracts or body liquids, PET, fluorescence imaging, or biochemical assays.

VOI	volumes of interest

WATERGATE	water suppression by gradient-tailored excitation
WEFT	water-eliminated Fourier transform
WET	water suppression enhanced through T_1 effects

Introduction

Nuclear magnetic resonance spectroscopy (NMR) has a long history that reaches back to 1945 when the phenomenon of nuclear magnetic resonance was experimentally verified in condensed matter for the first time. After successful applications of NMR in analytical chemistry, structural biology, and initial magnetic resonance imaging (MRI) trials, localized *in vivo* magnetic resonance spectroscopy (MRS) was finally introduced during the 1980s. It has evolved during the past 25 years in terms of localization quality, spatial resolution, acquisition speed, artifact suppression, number of detectable metabolites, and quantification precision, and has profited especially from the significant increase of magnetic field strength that recently became available for *in vivo* investigations. Today it allows for noninvasive determination of tissue concentrations of various metabolites and compounds in animals or humans and is applied for clinical diagnostics as well as physiological research.

Basic Principles

Chemical Shift and Spectral Resolution

The precession frequency ω_0 of a nuclear spin, which is known as the Larmor frequency, depends mainly on the

field strength of the external magnetic field B_0 and an intrinsic property of the nucleus – its gyromagnetic ratio γ (^1H : $\gamma/2\pi = 42.58$ MHz/T):

$$\omega_0 = -\gamma B_0 \quad (1)$$

From this equation it is obvious that different atomic nuclei have different Larmor frequencies at the same field strength and thus can be distinguished by NMR. But even more importantly shielding of the external magnetic field strength by an electron orbital is different for distinct molecules and even for distinct atoms of the same kind inside one molecule. This leads to slightly different Larmor frequencies ω for nuclei of the same kind that have different chemical environments. This effect – the so-called chemical shift δ – enables distinction of protons bound to different metabolites and compounds and therefore also the estimation of tissue concentrations of the related molecules based on *in vivo* ^1H MRS. The chemical shift is reported consistently for ^1H NMR and *in vivo* ^1H MRS as the difference from that of the reference substance tetramethylsilane (TMS). It can be specified directly either in hertz, which is field strength dependent, as

$$\delta_{\text{Hz}} = \omega - \omega_{\text{TMS}} \quad (2)$$

or in parts per million (ppm), which does not depend on the field strength (**Figure 1**) and is calculated as follows:

$$\delta_{\text{ppm}} = (\omega - \omega_{\text{TMS}})/\omega_0 \quad (3)$$

By convention the chemical shift of TMS is defined to be 0 ppm. However, all *in vivo* MR scanners set the water resonance – by far the largest resonance peak visible *in vivo* by ^1H MR spectroscopy – to a relative frequency

Figure 1 Field strength dependence of chemical shift and spectral separation illustrated by single voxel spectra ($T_E = 18$ ms; 1.5 T: PRESS; 7 T: STEAM) from healthy white matter in the human brain. The chemical shift between NAA and Cr is approximately 1 ppm at 1.5 T (left and middle) and 7 T (right), whereas the chemical shift between these two resonances is 65 Hz at 1.5 T and 300 Hz at 7 T. The resonances of interest are distributed over a range of 250 Hz at 1.5 T to 1250 Hz at 7 T. To illustrate this effect, the left 1.5 T spectrum and the 7 T spectrum are scaled to the same frequency axis. It leads to a largely improved spectral separation and a number of distinguishable resonance lines at 7 T (right) in comparison to 1.5 T (middle). Cho, choline containing compounds (GPC & PCh); Cr, creatine; Glx, glutamine and glutamate; ml, myo-inositol; NAA, *N*-acetylaspartate.

of 0 Hz for internal calibration purpose. Spectra are shifted to meet the TMS convention only after the acquisition.

Almost all proton resonances occur in a frequency range of 10 ppm in comparison to 30 ppm for ³¹P resonances and 200 ppm for ¹³C resonances. Depending on the field strength this corresponds to spectral widths (SWs) of 500 Hz at 1.5 T to 3200 Hz at 9.4 T. Water resonates approximately in the middle of the relevant frequency range at 4.7 ppm. Protons bound to carbons in aromatic rings and nitrogen atoms resonate at higher chemical shifts and protons bound to carbons in most aliphatic compounds at lower chemical shifts than water. Protons bound to oxygen atoms are usually not visible. *In vivo* ¹H MRS is mostly based on aliphatic protons that give rise to resonance lines between 0 and 4 ppm. Approximately 20 metabolites reach tissue concentrations that enable *in vivo* detection. To resolve the resonance lines sufficiently, the FID has to be sampled sufficiently long and with a minimum sampling rate F_{Nyquist} that is twice as high as the highest offset frequency $\pm F$. The resulting spectral resolution $\Delta\nu$ is thus determined by the number of sampling points N applied to sample a certain SW:

$$\Delta\nu = \text{SW}/N = F_{\text{Nyquist}}/N = 1/N\Delta t = 1/T_{\text{acq}} \quad (4)$$

Since the maximal sampling rate F_{Nyquist} and hence the minimal sampling interval Δt depend on the analog-to-digital converter and are fixed, the spectral resolution is inversely proportional to N times Δt , which equals the acquisition time. In reality 8 or 16 times over sampling is applied to improve the SNR of the digitized signal as well as to suppress high frequency components. To avoid truncation artifacts (sinc wiggles) it is also favorable to sample the signal until it nearly completely decays. Hence acquisition times for *in vivo* ¹H MR spectroscopy are typically between 250 and 2000 ms long.

Considering the small frequency range of interest, the relatively high number of detectable metabolites along with multiplet splitting due to J -coupling, rather broad resonance lines due to short T_2 relaxation times and B_0 inhomogeneities, *in vivo* ¹H MRS suffers from substantial spectral overlap. This problem improves significantly if high magnetic field strengths are used since spectral separation, for example, chemical shift in hertz, scales linearly with B_0 (Figure 1). Other approaches to reduce spectral overlap are spectral editing and 2-D spectroscopy methods. Spectral overlap is in general less an issue for ³¹P and ¹³C *in vivo* MRS.

Sensitivity and Relaxation

Pulsed nuclear magnetic resonance as used for *in vivo* MRS induces transitions between two Zeeman energy levels by irradiating electromagnetic waves of the corresponding

Larmor frequency. Hence, the sensitivity of an NMR experiment depends on the population difference Δn between these two Zeeman energy levels, which is defined by the Boltzmann regime:

$$\Delta n = \frac{\gamma \hbar B_0}{2k_B T_s} \quad (5)$$

From eqn [5] the relative sensitivities of ¹H, ³¹P, and ¹³C can be derived (Table 1).

Among these three nuclei relevant for natural abundance *in vivo* MRS, protons are clearly most sensitive. In addition, the population difference increases linearly with increasing field strength which leads also to a linear increase of sensitivity with increasing field strength. Furthermore, also the Larmor frequency and hence according to Faraday's law of electromagnetic induction the induced signal scales linearly with field strength. However, this is valid as well for sample dominated noise. Thus, in total, SNR increases linearly with field strength.

The SNR of a real spectrum also depends on the relaxation behavior of the investigated molecules. Although relaxation mechanisms are complex and complicated even further by compartmentalization, it has been shown that *in vivo* T_2 relaxation is dominated by local susceptibility effects and T_1 relaxation by dipole-dipole interactions. This explains the empirical finding of T_2 relaxation times that shorten especially for small and mobile molecules with increasing field strength, whereas T_1 relaxation times especially for large and immobile molecules lengthen. Table 2 lists typical relaxation times at different field strength for the most prominent resonance lines of an *in vivo* ¹H brain spectrum. *In vivo* transverse relaxation times for protons are usually longer than these of ³¹P nuclei and shorter than those of ¹³C nuclei. Longitudinal relaxation times for ¹³C and ³¹P nuclei are typically longer than those of protons.

Methods

Localization

In vitro NMR samples whether liquid or solid are in general small and thus investigated as a whole with NMR probes that are basically wrapped around them. In contrast to that, preselection of a volume of interest is desired for most applications of *in vivo* ¹H MRS to obtain the necessary spatial specificity and to avoid artifact sources.

The simplest approach is based on surface coils with a field of view (FOV) that matches the region of interest (ROI). However, the resulting inhomogeneous B_1 field makes any trial of quantification difficult and sufficiently high sensitivity can just be reached if the ROI is located close to the body surface. The approach is in general more feasible with a low external magnetic field strength, and nuclei with small gyromagnetic ratios since the

Table 1 Properties of nuclei visible *in vivo*

Nucleus	Spin quantum number	Gyromagnetic ratio $\gamma/2\pi$ (MHz T ⁻¹)	Natural abundance (%)	Relative sensitivity for equal number of spins and constant B_0	Relative sensitivity corrected for natural abundance

B_1 transmit-and-receive field becomes the more inhomogeneous the shorter the wavelength of the electromagnetic waves. Furthermore the high sensitivity that proton MRS offers in comparison to ³¹P and ¹³C MRS allows for the acquisition of MR spectra from small volumes of interest (VOI).

Hence a number of gradient-based 3-D localization sequences have been developed for *in vivo* proton MRS. They are mostly combined with volume coil transmission and either volume, array, or surface coil reception.

The most common localization sequence is known as point resolved spectroscopy (PRESS) (**Figure 2(a)**) and applies one slice-selective 90° excitation pulse and two slice-selective 180° refocusing pulses. Slice selection is based on simultaneous application of an RF pulse and a gradient. All three selected slices are perpendicular. Hence the second spin echo, the one that is acquired, originates from the intersection of these three perpendicular slices and thus from a cuboid volume. PRESS retains the full signal amplitude, but depending on the maximum B_1 field and RF pulses minimum echo times may become too long to obtain signal from metabolites with very short T_2 relaxation times. In addition the chemical shift displacement artifact is especially problematic for refocusing pulses (compare the section ‘Artifacts’). Both effects become more severe with increasing magnetic field strength.

An alternative method, which achieves very short echo times and reduces chemical shift displacement, is the stimulated echo acquisition mode (STEAM) (**Figure 2(b)**). Here, three perpendicular slices are selected by three consecutive slice-selective 90° RF pulses, the first two being separated by half the echo time $T_E/2$ and the second and third by the mixing time T_M . After a delay $T_E/2$ after the last 90° pulse a stimulated echo occurs. Three further FIDs and four spin echoes that are also produced by the sequence at various time points are suppressed by phase cycling and spoiler gradients. The major disadvantage of this localization scheme is its intrinsic 50% SNR loss.

For use with very inhomogeneous B_1 fields, 3-D localization by adiabatic selective refocusing (LASER) (**Figure 2(c)**) was introduced. Similar to PRESS a spin echo is recorded. The slice-selective 90° RF pulse is substituted by a nonselective adiabatic half-passage pulse (AHP). To achieve 3-D localization three pairs of slice-selective adiabatic full passage pulses (AFP) select three perpendicular slices. The two pulses of each pair select the same slice – the second AFP pulse of each pair refocuses the nonlinear phase over the slice introduced by the first AFP pulse. Advantages of this sequence are high B_1 inhomogeneity tolerance, small chemical shift displacements, and a spin lock effect that leads to prolonged T_2 relaxation times ($T_{2\rho}$). However, especially at high field in human MR scanners either the echo times

Figure 2 Localization sequences for *in vivo* ^1H MRS: PRESS (a), STEAM (b), LASER (c), and ISIS (d). The first rows present RF pulses applied, the second row shows the induced NMR signals, and the third to fifth rows illustrate the necessary gradient pulses along three perpendicular directions (white: slice selection gradient; gray: refocusing gradient; black: spoiling gradient). For detailed descriptions of these sequences please refer to the relevant paragraph.

become long or the pulses are driven in the nonadiabatic regime since maximum B_1 values are subject to tight limitations. Whereas in high-field animal MR scanners, short echo times down to 20 ms along with sufficient B_1 insensitivity can be achieved.

All three so far described localization methods are single shot methods; that is, the complete 3-D localization is achieved in a single repetition time. Another possibility which is usually utilized for *in vivo* ^{31}P MRS but might get more important for ^1H MRS when using ultrahigh field clinical MR scanners is image-selected *in vivo* spectroscopy (ISIS) (Figure 2(d)). Three slice-selective adiabatic inversion pulses invert the phase in three perpendicular slices, and are followed by excitation based on a nonselective AHP pulse. For 3-D localization eight encoding steps are needed that use different combinations of zero to all three inversion pulses to define the intersecting cuboid. Although this sequence shows a good B_1 inhomogeneity tolerance along with minimal SNR loss and J -coupling evolution, a linear phase gets introduced into the resulting spectra due to the acquisition delay and the sequence is prone to flow and motion artifacts.

Recently mixed forms of the previously described localization sequences have been introduced. Examples are semi-LASER that combines a nonadiabatic slice-selective 90° pulse with two pairs of AFP pulses, or SPECIAL, a combination of 1-D ISIS encoding and a 2-D selective spin-echo experiment.

The previously described localization techniques can be combined with slice-selective presaturation which is commonly referred to as outer-volume suppression (OVS) (Figure 3(a)) to further enhance localization and to minimize artifact content of the spectra. One OVS band utilizes a slice-selective saturation pulse with a subsequent crusher gradient. Saturation pulses of the latest generation are frequency-modulated RF pulses and achieve substantially higher bandwidths (BW) at the same B_1 scaling in comparison to excitation or refocusing pulses since they do not need to have a linear phase response. For most applications multiple overlapping OVS bands are utilized to adjust the geometry of the presaturated area toward the artifact sources, for example, the skull or toward the volume of interest, for example, to avoid anomalous J -modulation in single voxel MRS (see the section 'Artifacts'). To achieve

Figure 3 Suppression sequences for *in vivo* ^1H MRS: single outer volume suppression (OVS) element and spatial arrangement of multiple OVS bands for brain MRSI (a), single presaturation-based water suppression elements (b), single inversion recovery-based water suppression element (c), frequency-selective dephasing based on BASING for water suppression (d), and numerically optimized flip angles and delays for the T_1 and B_1 insensitive water suppression scheme VAPOR (e). While OVS is based on spatially selective pulses (indicated by slice selection gradient in (a)) all other techniques rely on frequency-selective RF pulses (indicated by H_2O in (b)–(e)). Water suppression based on presaturation, inversion recovery, and VAPOR is applied before excitation, whereas BASING is applied during the spin echo phase (slice selection gradient: white; refocusing gradients: gray; spoiler gradients: black) (d). The performance of VAPOR can be further improved by an iterative flip angle optimization of α , which has a starting value of 90° , just prior to the measurement.

T_1 - and B_1 -insensitive OVS, two or more saturation pulses per geometrically described OVS band have to be utilized and its flip angles have to be numerically optimized.

Suppression

Water is the most abundant molecule in living tissue and hence the base of most MRI examinations. However, the resulting ^1H MRS water signal is approximately 10 000 higher than that of the metabolites of interest. Although modern 16-bit analog-to-digital converters are able to adequately digitize the low-intensity metabolite signals in presence of the high-intensity water signal, the resulting baseline distortion and modulation sidebands (see the section ‘Artifacts’) obscure metabolite quantification. Hence almost all *in vivo* ^1H MRS applications utilize water suppression schemes. Among different possibilities three approaches have gained practical significance.

One is similar to the presaturation based approach (Figure 3(b)) used in OVS as described previously. The only difference is that the saturation pulse is not spatially but frequency selective and excites a small frequency band of 50–300 Hz centered on the water resonance (CHESS). It is also followed by a spoiler gradient. Presaturation elements are in general applied before the

localization sequence, except for STEAM which allows for additional CHESS elements during the mixing time between the second and third 90° pulse. As for OVS, best results are obtained if three (WET (water suppression enhanced through T_1 effects)) to eight (VAPOR (variable power radio frequency pulses with optimized relaxation delays) presaturation elements with numerically optimized flip angles and delays considering the relevant T_1 and B_1 range are used (Figure 3(e)).

Water suppression can also be achieved by exploiting different T_1 relaxation times on their own (Figure 3(c)). Basic sequences are based on a frequency-selective 180° inversion pulse followed by a delay that is optimized such that the M_z magnetization of water is zero at the time of excitation. Two sequentially applied inversion pulses enable already T_1 -insensitive suppression. For the detection of metabolites with chemical shifts close to that of water, methods such as WEFT or DEFT were developed, which use broadband inversion pulses instead of frequency-selective inversion pulses. Although similar to VAPOR and WET, inversion recovery-based water suppression methods do not utilize spoiler gradients.

A completely alternative approach is frequency-selective dephasing in the spin-echo period. Different implementations of this concept such as WATERGATE,

MEGA, or BASING (Figure 3(d)) have been suggested. For the latter a spoiler gradient is applied to dephase all spins. This dephasing element is followed by a frequency-selective refocusing pulse centered on the water frequency, which rephases exclusively water spins. Finally a gradient of opposite sign in comparison to the first one is applied to rephase all spins except water that is dephased again. If minimum or maximum phase-pulses are used for selective refocusing the phase distortion has to be corrected for by a second BASING pulse. This also improves the suppression quality. Although frequency-selective dephasing-based water suppression methods are powerful, they are just compatible with long echo times.

Not only intensities of water but also of lipid signals from fat-rich tissue such as bone marrow or subcutaneous fat are substantially higher than those of the signals of interest. Lipid signals hamper metabolite quantification due to baseline distortion and might even completely obscure certain metabolite peaks. Signal from skull lipid might end up in a single voxel MRS spectrum of otherwise lipid free brain tissue, if the chemical shift displacement artifact shifts the excited volume for lipid into the skull area. This can be avoided by inner-volume saturation using a highly selective B_1 - and T_1 -insensitive OVS or by changing the direction of the chemical shift displacement direction for lipids. In the case of brain MRSI an additional problem is the point-spread function that causes spreading of the lipid signal from the skull or other lipid-rich tissue into neighboring voxels. Although for low resolution, MRSI bad lipid suppression might cause contamination of spectra from all voxels, for high resolution, MRSI spectral distortions occur more locally. However, efficient lipid suppression is mandatory for most MRSI applications. It can be achieved using basically the same approaches as were described previously for localization enhancement (OVS) and water suppression (frequency-selective presaturation, inversion recovery or dephasing). Any of these methods can also achieve simultaneous water and lipid suppression. To that the difference in T_1 has to be considered and frequency-selective suppression sequences have to be combined with RF pulses with two distinct passbands at the water and lipid frequency. Finally, outer volume suppression and water suppression sequences might be interleaved.

Shimming

Inside an empty MR scanner the static magnetic field is highly homogeneous. However, the introduction of any phantom, animal, or human causes significant B_0 inhomogeneities due to susceptibility differences inside the body or phantom. Separate shim coils – an essential part of every modern MR scanner – can partly compensate for the introduced B_0 inhomogeneities. However, the

effect of microscopic and macroscopic susceptibility differences on B_0 homogeneity increases with increasing field strength. Thus especially at high and ultrahigh fields efficient B_0 inhomogeneity correction, shimming, is crucial to obtain narrow spectral line widths. The latter is an absolute necessity to obtain both a sufficient spectral resolution and sufficient SNR in the resulting spectra. The better the shim quality the more reliable is spectral quantification of smaller resonance lines and J -coupled metabolites especially in the presence of significant spectral overlap such as occurs for *in vivo* ^1H MRS. Previous advances in shimming include an increasing number of shim coils at high field strength to achieve not only linear but also second and third order B_0 inhomogeneity correction. In addition, the maximum available shim currents have to be substantially higher at 3 and 7 T in comparison with lower field strengths to generate correction fields large enough to compensate the B_0 inhomogeneities. Last but not least, efficient algorithms are necessary to compute optimal shim currents. Considering the large number of interdependent shim terms that need to be determined for efficient higher order shimming, manual or automatic iterative shim adjustments are time consuming and might not converge. Much better alternatives are the acquisition of B_0 inhomogeneity projections along different directions (FASTMAP) or even the acquisition of entire B_0 inhomogeneity maps. Based on these data fast optimization routines can determine the optimal shim currents. FASTMAP is significantly faster than B_0 -mapping and advantageous if the organ geometry is similar to a sphere, ellipsoid, or cylinder as for the human brain. It has also previously been proved to work at high and ultrahigh field strength. In contrast to that, B_0 inhomogeneity mapping showed better results if complicated susceptibility distributions and organ geometries are present as, for example, in the human heart.

Postprocessing and Quantification

The only two absolutely required postprocessing steps are the fast Fourier transform (FFT) which converts the FID into a spectrum with resonance lines along a frequency axis and correction of the phase to achieve pure absorption lines in the real part of the spectrum. Owing to the simultaneous exponential (due to T_2 relaxation) and Gaussian (due to B_0 inhomogeneities) decay of the NMR signal the resulting resonance lines have Voigt line shapes. To improve the appearance of an *in vivo* ^1H MR spectrum additional water filters, zero filling to increase the spectral resolution, additional exponential or Gaussian filtering for SNR enhancement or baseline correction methods such as polynomial baseline fitting and subtraction, convolution difference, or broadband suppression filters might be

Figure 4 Metabolite basis simulated by GAMMA for PRESS ($T_E = 35$ ms; 3 T). Spectral quantification is based on fitting a linear combination of such metabolite specific basis spectra. Since the phase evolution for all J -coupled resonances depends on echo time, field strength, sequence, and partly also RF pulses, a suited metabolite basis set has to be simulated that is in accordance with the acquisition parameters. Abbreviations are as given in Figure 1; Ala, alanine; Asc, ascorbate; ASP aspartate; GABA, gamma aminobutyric acid; Glc, glucose; Gln, glutamine; Glu, glutamate; GPC, glycerophosphocholine; GSH, reduced glutathione; Lac, lactate; NAAG, *N*-acetylaspartylglutamate; PCh, phosphocholine; PE, phosphoethanolamine; scylloI, scyllo-inositol; Tau, taurine.

applied. However, all these ‘cosmetic’ corrections might hamper metabolite quantification.

The intensity of the FID in the time domain as well as the area underneath a resonance line in the frequency domain is proportional to the number of spins that contribute to the signal and hence also to the tissue concentration of the respective metabolite. To access this information different approaches can be chosen. The simplest one is peak integration in the frequency domain based on integration boundaries. A bit more advanced is fitting of Voigt lines to the spectrum which is mostly based on some prior knowledge such as approximate frequencies and phases of the resonance lines (using software such as AMARES/JMRUI). Both approaches are problematic in the presence of spectral overlap and macromolecular baselines and do not consider phase evolution of J -coupled metabolites. Hence state-of-the-art quantification methods for *in vivo* ^1H MRS fit a linear combination of measured or simulated (e.g., GAMMA library) basis spectra of the most abundant 20 metabolites

(**Figure 4**) along with a model of the macromolecular baseline. The metabolite basis includes all necessary information about weak and strong scalar coupling and thus field strength, echo-time, and sequence-dependent phase evolution and multiplet splitting of resonance lines (**Figure 4**). Since all proton resonances originating from the same metabolite are considered in the individual basis spectra, spectral overlap can be fairly well decomposed. Fitting can be performed in the frequency domain (LC Model) (**Figure 5(a)**), time domain (QUEST/JMRUI) or using information from both domains (TDFD fit). In general all fitting should be done on complex data, that is, the phase of the spectrum is included as a fitting parameter. Further parameters include exponential and Gaussian line broadening terms. If entire echo-time or T_1 relaxation series were acquired T_1 and T_2 relaxation times can be also included as fit parameters (IDAP). The quality of the baseline fit, the appearance of the residual, error estimates based on Cramer–Rao lower bounds (CRLB) (**Figure 5**), systematic correlations

Figure 5 LC Model fit of a single voxel PRESS spectrum from human brain white matter based on the metabolite basis depicted in Figure 4(a). The original spectrum is overlaid by the fitted curve (a, red). Underneath the spectrum the spline baseline fit is indicated. The top row (a) shows the fitting residual. In the right table fitting results including fitting error estimates are summarized (a). From equivalent fitting results or simple line integration metabolite distribution maps such as shown for NAA can be derived from MRSI data (b). Voxels created by phase encoding (red grid) as well as volume selection by PRESS (green box) and additional outer volume suppression elements (blue) are depicted in the (top row, b), whereas localization is reflected in the NAA map (bottom row, b).

revealed by the Fisher information matrix, and the user dependence of fitting results are important quality criteria.

Although decomposing an acquired spectrum into the contributing metabolite basis and determining the individual signal amplitudes is an important step toward metabolite quantification, further considerations are necessary before quantification results can be reported. Tissue concentrations of various molecules and compounds can be either given as ratio to a reference metabolite such as total creatine (relative quantification) or in millimolar (absolute quantification). Although relative quantification is widely used, it has the major disadvantage of ambiguities whenever several metabolite concentrations change simultaneously, as is the case for most diseases. Hence absolute quantification is an indispensable tool to precisely determine metabolite changes for clinical diagnostics and physiological studies. However, corrections for a number of side factors that also influence the signal amplitude are mandatory and the metabolite signal of interest has to be compared to a reliable calibration standard before millimolar concentrations can be given. Side factors include voxel size, number of averages, coil load, receiver gain, transmit-and-receive B_1 fields, pH, temperature, as well as T_1 and T_2 relaxation times. The golden standard for absolute quantification of *in vivo* ¹H MR spectra is the internal water reference

method, which is essentially nothing other than relative quantification with unsuppressed water as reference metabolite under the assumption of a stable and tissue-specific water content. The big advantage of this method is that except individual T_1 and T_2 relaxation times all side effects are automatically considered. However, especially for clinical diagnostics it is unreliable since the tissue water content might change significantly, for example, in tumors or abscesses. Hence a number of phantom calibration methods based on a reference solution have been developed that considered a larger or smaller number of the known influence factors mentioned earlier. Both internal water reference and phantom calibration methods require additional measurement time (compare the section ‘Artifacts: modulation sidebands’). Hence recently it was suggested to use an artificial NMR signal injected by a little loop coil (ERETIC) which is acquired simultaneously with the real MR spectrum as reference.

Magnetic Resonance Spectroscopic Imaging

Similar concepts as used for MRI enable spatially resolved or multivoxel *in vivo* ¹H MRS known as magnetic resonance spectroscopic imaging (MRSI) or chemical shift imaging (CSI). All of the previously described localization and suppression schemes can be combined

Figure 6 Localization and acceleration sequences for *in vivo* ^1H MRSI: nonaccelerated 2-D MRSI based on slice-selective spin echo acquisition in combination with OVS (SELOVS) (a), the corresponding PSF (b) and k -space coverage (each dot corresponds to a phase encoding step) (c) and principles of various acceleration methods (c)–(f). k -space shuttering (c) leaves out the outermost k -space points. Sensitivity-encoded MRSI (d) applies sparse sampling, which results in an FOV reduction and fold-over artifacts in both phase encoding directions. Based on sensitivity maps for all elements of an array coil these folded MRSI data can be unfolded and a conventional MRSI data set and metabolites can be reconstructed. Multi-spin echo MRSI (e) acquires up to four echoes per repetition time T_R but suffers from T_2 weighting, which introduces an unfavorable point-spread function. Echo-planar MRSI is a gradient echo-based method that encodes spatial-spectral plane per T_R and hence an entire row in k -space. The encoding in the second spatial domain is based on conventional phase encoding (phase encoding gradients: striped; slice selection gradient: white; refocusing gradients: gray; spoiler gradients: black).

with phase encoding along one, two, or three dimensions (Figure 6(a)) to get a 1-D, 2-D, or 3-D MRSI dataset. The VOI selected by the localization method of choice is thereby subdivided into many smaller voxels (see Figure 5(b)). Additional localization schemes that are only based on slice-selective FID (FIDLOVS) or spin-echo acquisition (SELOVS) in combination with OVS for localization in the second and third dimensions (Figure 6(a)) might be advantageous to adjust the VOI to the geometrical shape of the investigated organ (Figure 3(a)) and hence, for example, access metabolite information from cortical brain tissue. Direct FID acquisition also minimizes T_2 dependent SNR loss in clinical high-field MR scanners. However, these techniques are not suited for MRSI of small organs located in the middle of the body, for example, the human prostate since for fold-over suppression a substantial FOV reduction is required.

The number of phase encoding steps that are performed along each dimension specifies the number of voxels along each dimension. The nominal voxel size along a certain

dimension can then be calculated dividing the FOV by the number of phase encoding steps. However, the nominal voxel size might substantially deviate from the effective voxel size. Only a finite number of k -space points are sampled in a discrete manner. To calculate spatial positions from the encoded phases a discrete FFT is performed. This leads to a convolution of the signal from a nominal voxel by the FFT of a rectangular function, which is a sinc function. Hence the signal from each nominal voxel would spread according to a sinc function into neighboring voxels and on the other hand a nominal voxel would also contain signal contributions from neighboring voxels (Figure 6(b)). This effect is called voxel bleeding and is caused by the individual point-spread function (PSF). At very low spatial resolutions the derived metabolite distributions might be totally misleading since each nominal voxel shows basically an average signal originating from large parts of the FOV. The higher the spatial resolution of an MRSI examination the smaller is the voxel bleeding effect caused by the PSF and the better the accordance of the derived metabolite maps with the anatomical reference. The side lobes of the

sinc function can be suppressed by k -space weighting/spatial apodization which can be applied either during the acquisition or as a postprocessing step. However, the main lobe of the sinc function would be further broadened. Hence spatial apodization suppresses long range voxel bleeding effects but further compromises the effective spatial resolution.

Owing to the intrinsic frequency dispersion of an MR spectrum, frequency encoding cannot be used. In comparison to MRI, MRSI is hence fairly slow since per repetition time T_R only one k -space point is sampled instead of an entire row of k -space points as for imaging. However, MRSI is still substantially faster than acquiring every voxel separately, since the number of voxel corresponds to the number of averages per voxel. Considering that a minimum of 64–128 averages per voxel is required to gain sufficient SNR for ¹H single voxel MRS, a medium resolution 2-D MRSI examination enables additional spatial information without major scan time prolongation. However, scan times can become very long for high spatial resolution, multislice or 3-D MRSI that aims at covering an entire organ. To overcome this problem different acceleration schemes were proposed that are based on three major strategies: (1) sample less k -space points, (2) sample more than one k -space point per repetition time, and (3) shorten the repetition time.

The simplest form to follow strategy (1) is to reduce the number of sampled k -space points by reducing the FOV to the minimal possible size. This can be obviously achieved by combining MRSI with the previously described 3-D localization methods (Figure 2). Another way to reduce the total number of sampled k -space points is to apply a spherical or elliptical k -space shutter, which means that only the central k -space points are sampled and the outermost are left out (Figure 6(c)). This decreases the spatial resolution but hardly affects the SNR. A more advanced method is known as sensitivity encoded MRSI (SENSE-MRSI), which is basically the analog to parallel MRI (Figure 6(d)). Here the k -space is sampled sparsely, for example, only every second k -space point is considered (Figure 6(d), top left). This results in a partial coverage of the desired FOV and hence in fold-over along all phase encoding dimensions (Figure 6(d), top right). With the help of array coils and sensitivity maps acquired for each individual small coil element (Figure 6(d), bottom left) the fold-over can be resolved and conventional metabolite maps can be reconstructed (Figure 6(d), bottom right). For an acceleration factor n it is assumed that each signal in a voxel of the fold-over map $S_{\text{fold-over}}$ can be described as a linear combination of n overlapping signals $S_{\text{unfold},1}$ to $S_{\text{unfold},n}$ weighted by the individual sensitivities C_1 to C_n of one coil element at these n spatial positions:

$$S_{\text{fold-over}} = C_1 S_{\text{unfold},1} + C_2 S_{\text{unfold},2} + C_3 S_{\text{unfold},3} + \dots + C_n S_{\text{unfold},n} \quad (6)$$

If a sufficient number of coil elements exist a system of linear equations defines the origin of the individual signal contribution unambiguously and the fold-over metabolite maps can be unfolded. This method neither compromises spatial nor spectral resolution, but the possible acceleration depends on array size and field strength.

A second group of MRSI acceleration methods aims at acquiring all k -space points but more than one during one repetition time. The simplest approach is to record multiple spin echoes instead of only one during each T_R (Figure 6(e)). However, the spacing between refocusing pulses has to be sufficiently long to avoid truncation artifacts and to reach a sufficient spectral resolution. Hence echo times become very long and, due to fast T_2 relaxation, the signal amplitude of the consecutive echoes decreases quickly. Hence this method introduces heavy T_2 weighting and similar to k -space shuttering decreases the spatial resolution. It is all together rather inappropriate for quantitative MRSI. More advanced methods are echo-planar spectroscopic imaging (EPSI) – a gradient echo method – and spiral MRSI. The concept behind EPSI is very similar to echo-planar imaging with the only difference that the readout gradients are not separated by phase encoding blips and the chemical shift freely evolves in time (Figure 6(f), left). Hence instead of a spatial plane rather one spatial dimension along with the spectral dimension is encoded in one repetition time (Figure 6(f), right). Limited gradient strength can limit the achievable spectral bandwidth, which becomes a problem, especially at high field strengths. Otherwise high acceleration factors are possible.

Another possibility to accelerate MRSI is to shorten the repetition time significantly thus imitating steady-state free precession methods as used for dynamic MR imaging. To maximize SNR efficiency, that is, the SNR per unit time, the flip angle of the excitation pulse has to be numerically optimized based on the T_1 relaxation times of the metabolites of interest. However, at high SNR efficiencies and high acceleration factors the time to sample the FID or spin echo is basically too short to achieve a favorable spectral resolution. In addition, truncation of the first points of the FID or spin echo introduces a strong linear phase into the spectra. Altogether SSFP-based MRSI methods are rather more suited for *in vivo* ¹³C MRS than for *in vivo* ¹H MRS.

Advanced In Vivo ¹H MRS Methods

To reduce spectral overlap and to increase the number of detectable metabolites especially at low field strength as used in a clinical environment, a number of editing and 2-D spectroscopy methods have been adopted for *in vivo* ¹H MRS. All methods exploit differences in scalar coupling between metabolites with overlapping resonance lines.

J -difference editing sequences exploit differences in phase evolution of one of the coupled spins in the presence and absence of frequency-selective refocusing pulses applied on one of the coupling partners in the same molecule. The difference of the two acquired spectra usually shows the J -coupled metabolite that was overlaid by larger mostly uncoupled metabolite resonances, which become visible if both recorded spectra are summed up. A popular application of J -difference editing is GABA editing (Figure 7(a) and 7(b)). The drawback of difference editing is that a two-shot method is prone to phase differences introduced by flow and motion.

Alternatively multiple quantum coherence editing might be applied, which can achieve editing during a single shot. It is based on the principle that single quantum coherence of a J -coupled spin system can be converted into other coherences, for example, zero and double quantum coherence, dephased, turned back to single quantum coherence, and refocused. Since uncoupled spins cannot form multiple quantum coherences that could be dephased, the final refocusing gradient in reality dephases the transverse magnetization and hence the hidden J -coupled metabolite becomes visible. Depending on the adjustments of delay duration and

refocusing gradients certain coherence transfer pathways specific for a certain metabolite can be selected. However, the signal amplitude of the resulting edited spectrum is at maximum 50% of the original one. The higher the coherence orders that are involved, the lower is the resulting intensity of the remaining signal. Finally it has to be mentioned that not only homonuclear but also heteronuclear scalar couplings can be exploited for editing. One example is proton-observed carbon-edited spectroscopy (POCE).

For most applications it would be favorable to detect all metabolites at once instead of being restricted to the one or two edited metabolites. This can be achieved by improving the spectral resolution by introduction of a second frequency axis. Although there are many 2-D NMR sequences, not all of them can be realized in the presence of short T_2 relaxation times, low tissue concentrations of the metabolites of interest, and the need for localization and solvent suppression and thus *in vivo*. Owing to its simplicity especially JPRESS and COSY have proven their practical applicability to physiological research. For JPRESS basically an echo-time series is recorded and subsequently a 2-D FFT is applied. Along the indirect domain, the J -splitting is encoded, whereas

Figure 7 J -difference editing for GABA detection: simulated (a) and *in vivo* (b) results and 2D JPRESS metabolite basis spectra that are used to fit according *in vivo* 2D JPRESS spectra (c). J -difference editing is a two-shot 1D ^1H MRS method that is based on the phase difference of GABA in spectra with the editing pulse switched on or off. The difference spectrum shows GABA, but none of the overlapping resonance lines. In contrast, 2D JPRESS is a method that spreads the J -coupled multiplets along two dimensions thus reducing the spectral overlap as indicated by the shown basis spectra. For detailed information about both methods please consult the original publications of Kaiser LG, Young K, Meyerhoff DJ, Mueller SG, and Matson GB (2008) A detailed analysis of localized J -difference GABA editing: Theoretical and experimental study at 4 T. *NMR in Biomedicine* 21: 22–32 for J -difference editing, and Schulte RF and Boesiger P (2006) ProFit: Two-dimensional prior-knowledge fitting of J -resolved spectra. *NMR in Biomedicine* 19: 255–263 for prior-knowledge fitting of 2D JPRESS spectra. Reproduced with permission.

the direct dimension shows the conventional chemical shift (**Figure 7(c)**). The basic COSY sequence consists of two consecutively applied 90° pulses that are separated by an evolution time which is incremented to encode the second frequency domain. The principle behind COSY, which stands for correlation spectroscopy, is that for homonuclear *J*-coupled spins polarization is transferred from one coupling partner to the other. This is achieved by the second 90° pulse, the mixing pulse, only for two *J*-coupled spins which develop antiphase coherence during the first evolution period. The spectrum would show a diagonal with all chemical shifts visible in a 1-D spectrum and in addition cross peaks with their own frequency along the direct frequency domain and the resonance frequency of the coupled spin along the indirect frequency domain. An important step toward establishing 2-D resolved *in vivo* MRS was the recent introduction of fitting a 2-D metabolite basis to *in vivo* 2-D MR spectra for quantification, which eventually enabled access of the full information content (ProFit) (**Figure 7(c)**).

Artifacts

In vivo ¹H MRS is prone to several artifacts that might mislead the interpretation of the resulting spectra. The most common of them are reviewed in this Section.

Ghosting

Ghosting is caused by water signal stemming from outside the VOI, which is not suppressed by the water suppression. Owing to strong *B*₀ inhomogeneities, water may have resonance frequencies that lie outside the suppression window and may be also insufficiently spoiled during the localization sequence. Phase cycling, a shim volume of sufficient size and good shim convergence, robust localization and spoiling, as well as a *T*₁ and *B*₁ insensitive water suppression can help to avoid this problem.

Modulation sidebands

Gradient induced modulation sidebands have their origin in insufficient water suppression and local fluctuations of the *B*₀ field due to gradient vibrations. If the residual water peak is large, additional antiphase peak pairs occur symmetrically at both sides of the water resonance. Multiple modulation sideband pairs might occur. Since their intensity and frequency can be similar to those of real resonance lines water modulation sidebands can be mistaken as real peaks. Since gradient vibrations can hardly be further reduced, an efficient *T*₁ and *B*₁ insensitive water suppression is the most obvious answer to this problem. Other approaches include cancellation of modulation sidebands due to adding up two MRS

examinations with opposite gradient directions or using postprocessing based methods.

Chemical shift displacement

The so-called chemical shift displacement artifact reflects the fact that the selected volume is displaced in all three dimensions according to the difference in Larmor frequency for differently shielded protons bound to distinct molecules. Hence, it distorts metabolic information by rendering the selected volume inconsistent across different metabolites, such as water and fat, giving rise to anomalous *J*-modulation, and causing signal cross-talk from peripheral signal sources, for example, lipid-rich tissue in brain MRSI. In addition, variation in the effective position of the PRESS box also compromises shimming and water suppression. Chemical shift displacement Δx is caused by tight restrictions in the maximum *B*₁ field strength and hence BW limitations of conventional amplitude-modulated RF pulses, with approximately linear phase response, leading to confinements of the respective selection gradient strength (*G*_x). Owing to the combination of increasing spectral separation $\Delta\nu$ at the same shielding $\Delta\delta$ with decreasing achievable maximum *B*₁ values, chemical shift displacement scales with field strength *B*₀:

$$\Delta x = \frac{\Delta\delta \cdot B_0}{G_x} = \frac{\gamma \cdot x \cdot \Delta\delta \cdot B_0}{2\pi \cdot BW} = \frac{2\pi \cdot \Delta\nu}{\gamma \cdot G_x} = \frac{x \cdot \Delta\nu}{BW} \quad (7)$$

All gradient-based MRS localization techniques introduce a misregistration of the chemical shift-dependent excitation volumes (of size *x*), but this problem is particularly severe for slice-selective refocusing pulses. The use of frequency-modulated or adiabatic RF pulses for excitation and refocusing and additional OVS (inner-volume suppression) can improve the problem.

Anomalous J-modulation

For *J*-coupled metabolites, signal cancellations might occur that are caused by adding up signals with different phase evolution. These arise if due to chemical shift displacement, all resonance lines of a coupled spin systems (with different resonance frequencies) experience both refocusing pulses in certain parts of the excited volume and in other parts only one of the coupling partners experiences one or both refocusing pulses, whereas the other does not. This well-understood phenomenon is especially important for lactate detection, but also substantial for other coupled metabolites such as GABA or alanine, and can be avoided by saturation of the nonoverlapping parts of the excitation volumes by highly selective OVS.

Stimulated echoes

Owing to B_1 inhomogeneities, the effective flip angle of an applied RF pulse can differ substantially from its intended value. Owing to this effect stimulated echoes can be induced in areas remote to the volume of interest especially by refocusing pulses in spin-echo sequences. Sufficient spoiling, outer-volume suppression, and phase cycling can eliminate spurious stimulated echoes.

Flow and motion

Blood and CSF flow, as well as organ motion, might induce major phase fluctuations in the water and metabolite signal, respectively. This can lead to signal cancellation effects if multiple spectra are averaged without prior phase correction of each individual spectrum. Alternatively, in the case of organ motion the voxel of interest changes its position relative to the organ and thus diagnostic relevance could be questionable. Constructive averaging after phase correction of each individual spectrum, ECG and respiratory gating, volume tracking and saturation of inflowing CSF can significantly enhance spectral quality.

Introduction

In vivo nuclear magnetic resonance spectroscopy (or *in vivo* MRS as it has become known) is increasingly being used to provide direct, localized biochemical information on animal and human metabolism in health and disease. Dedicated systems for animal studies use magnetic fields ranging from 2.0 to 9.4 T. Most human MRS systems range from 1.5 to 2.0 T, although 4 T systems are available. Clearly these systems offer spectra with a quality and sensitivity no better than that obtained with high-resolution NMR systems from 30 years ago. However, even within these constraints, *in vivo* MRS has contributed greatly to our understanding of the metabolic processes associated with a wide range of clinical and metabolic disorders by providing researchers with information that could not be obtained previously even with tissue biopsies. The application of *in vivo* MRS has expanded rapidly in recent years and its value as a research tool depends on the organ under investigation as well as the nuclei being utilized. This article reviews the work carried out to date in *in vivo* MRS using ^{13}C , ^{19}F , ^{15}N , ^{23}Na and other less common nuclei.

A list of nuclei currently being used for *in vivo* biomedical research is shown in **Table 1**. Although many of these nuclei are routinely used in high-resolution

in vitro NMR spectrometers, their implementation in *in vivo* MRS systems required substantial technical development and many are available only to a handful of research groups around the world. This is partly due to the considerable cost associated with developing multi-nuclear capabilities into commercial systems. Accordingly, most commercial MR systems have very restricted spectroscopic capabilities, with ^1H and ^{31}P being the nuclei generally available. This has, of course, restricted the application of less common nuclei in biomedical research. A summary of the main areas of research and application of some of these nuclei is shown in **Table 2**. Results of many of these studies have made considerable contributions to important areas of clinical and biochemical research, while other studies have concentrated on demonstrating technical feasibility, although they suggest the prospect of major areas of future research.

In Vivo ^{13}C MRS

Whole-body ^{13}C MRS is potentially the most powerful tool available for the study of human metabolism *in vivo*. The nuclide's low natural abundance (1.1%) allows the study of important biological molecules such as glycogen and lipids, while at the same time allowing the use of ^{13}C -enriched compounds in dynamic measurements of intermediate metabolism. However, several technical issues need to be addressed before its implementation *in vivo*, including a second transmit channel, optimum localization and proton decoupling. The latter has been one of the major stumbling blocks for the application of *in vivo* ^{13}C MRS, because of the potential problem of power deposition during proton decoupling. This problem has now been addressed by the use of the newer pulse train decoupling sequences, which allow full decoupling of signals with low power deposition. The need for a second transmit channel with frequency synthesizer, phase modulator and power amplifier, together with the need for specifically designed $^1\text{H}/^{13}\text{C}$ coil systems, means that the actual cost of a standard *in vivo* scanner is substantially increased, hence limiting its availability. Thus, although many of the technical problems associated with the use of ^{13}C MRS *in vivo* have been overcome, it is still not routinely available to the great majority of research groups

Table 1 NMR characteristics of some nuclei of biomedical interest

Nucleus	Spin	Relative sensitivity	Natural abundance (%)	Observation frequency for ^1H observation at 100 MHz
^2H	1	9.65×10^{-3}	1.5×10^{-2}	15.35
^7Li	$\frac{3}{2}$	2.93×10^{-1}	92.58	38.86
^{11}B	$\frac{3}{2}$	1.65×10^{-1}	80.42	32.08
^{13}C	$\frac{1}{2}$	1.59×10^{-2}	1.11	25.14
^{15}N	$\frac{1}{2}$	1.03×10^{-3}	0.37	10.13
^{17}O	$\frac{5}{2}$	2.91×10^{-2}	0.04	13.56
^{19}F	$\frac{1}{2}$	8.3×10^{-1}	100	94.08
^{23}Na	$\frac{3}{2}$	9.25×10^{-1}	100	26.45
^{27}Al	$\frac{5}{2}$	2.06×10^{-1}	100	26.06
^{29}Si	$\frac{1}{2}$	7.84×10^{-3}	4.70	19.86
^{87}Rb	$\frac{3}{2}$	1.7×10^{-1}	27.85	32.72
^{129}Xe	$\frac{1}{2}$	2.12×10^{-2}	26.44	27.66

Table 2 *In vivo* applications of NMR spectroscopy

Nucleus	Application	Organ/tissue
¹³ C	Glycogen	Liver, muscle
	Amino acids, glucose	Brain
¹⁹ F	Lipids	Adipose tissue, liver
	Drug metabolism	Liver, brain, muscle
	Anaesthetics	Brain
	Phospholipids	Tumour
	Intracellular Ca ²⁺	Brain, kidney, spleen
¹⁵ N	Glucose metabolism	Brain
	Glutamine metabolism	Brain
²³ Na	Electrolyte balance	Muscle, brain, liver, heart
² H (D)	D ₂ O, methionine, glucose	Brain, adipose tissue, liver
	Choline	Kidney
²⁷ Al	Gastric emptying	Gut
¹²⁹ Xe	Lung volume	Lungs
¹⁷ O	Blood flow	Brain, liver
⁸⁷ Ru	Na ⁺ /K ⁺ -ATPase	Muscle
⁷ Li	Psychiatric disorders	Brain, muscle
¹¹ B	Therapy agents	Liver, brain, tumour
²⁹ Si	Breast implants	Liver

Application of *In Vivo* ¹³C MRS to Carbohydrate Metabolism

Carbohydrate metabolism is one area of research that has significantly benefited from *in vivo* ¹³C MRS since signals from sugar carbons occur in a region of the spectrum that is relatively unpopulated by other resonances. Using specific carbon labelling on different substrates, various metabolic pathways have been studied. Further information has been gained by labelling two adjacent carbon atoms within the same molecule; this produces a characteristic ¹³C–¹³C spin–spin coupling, helping to elucidate important information about particular enzyme pathways

Liver

The first *in vivo* experiments, performed in 1981, explored the potential application of ¹³C MRS to glucose/glycogen metabolism. Following infusion of ¹³C-enriched glucose in rats, well-resolved resonances from both glucose and glycogen could be observed, enabling the time course of the relative changes in concentration to be established simultaneously. One area of debate at the time was the degree of glycogen visibility in liver. It was initially thought that glycogen, being such a large macromolecule, would be only partly NMR 'visible'. However, the most recent consensus is that glycogen is in fact 100% visible and that ¹³C MRS can therefore provide reliable noninvasive measurements of hepatic glycogen concentrations over physiological ranges.

Glycogen repletion studies have been carried out in animals and humans. Infusions of [1-¹³C]glucose and [3-¹³C]alanine to fasted rats suggested that 30% of the total glycogen formed originated from the direct conversion of glucose in the short term. However, over the longer term, active glycogen synthesis from [3-¹³C]alanine occurred for a longer period of time, with a rate constant threefold higher than from [1-¹³C]glucose, implying greater efficiency of glycogen synthesis from the indirect route. These studies have also highlighted potential problems associated with substrate cycling, since following entry into the Krebs cycle the label may be assimilated into other pathways and then re-introduced into the gluconeogenic pathway. Definitive mechanisms of glycogen repletion therefore become difficult to assess *in vivo*, unless measurements are performed immediately following administration.

Human studies have concentrated on direct observation of glycogen repletion using natural abundance ¹³C or after administration of [1-¹³C]glucose. Early work compared pre- and post-meal hepatic glycogen repletion rates in individuals starved for 30 h showing repletion rates 3.8 times greater in the post-meal states compared with the fasted basal rate. Hepatic gluconeogenesis in healthy subjects and those with non-insulin-dependent diabetes mellitus (NIDDM) was also investigated by ¹³C MRS and conventional methods. Concentration of glycogen was lower in NIDDM patients compared to controls (**Figure 1**). Furthermore, following infusion of [6-³H]glucose, gluconeogenesis in the NIDDM subjects was found to be 60% greater than in control subjects and accounted for 88% of the total glucose production compared with 70% in the normal subjects. This suggests that increased gluconeogenesis accounts for the increase in whole-body glucose production in overnight-fasted NIDDM subjects.

¹³C MRS has also been applied to determine the metabolic alterations caused by glycogen storage diseases. Patients with glycogen type IIIA storage disease were shown to have increased levels of hepatic glycogen compared with normal volunteers. This disease manifests owing to the inactivation of amylo-1,6-glucosidase, which is required for glycogen hydrolysis. It was concluded that *in vivo* ¹³C MRS could play an important role in the assessment of other glycogen storage diseases where current clinical practice requires needle biopsies to be performed.

¹³C MRS has also been used to assess enzyme capacities and kinetics in animals. Following infusion of [1-¹³C]butyrate (90% enriched), rates of ketogenesis could be monitored by measuring the formation of acetoacetate and β-hydroxybutyrate within the carbonyl region of the ¹³C MR spectrum. Further studies of ¹³C-labelled fatty acids, such as [1,3-¹³C]butyrate, assessed the metabolic pathways of ketone body production

Figure 1 Typical *in vivo* ^1H -decoupled ^{13}C MRS spectra at 22.5 MHz of the C-1 position of liver glycogen from a control subject (a) and from a type II diabetic patient (b) 4 hours after a liquid meal. Reproduced with permission from Magnusson I, Rothman DL, Katz LD, Shulman RG, and Shulman GI (1992) Increased rate of gluconeogenesis in type II diabetes mellitus. *Journal of Clinical Investigation* 90: 1323–1327.

in fasted and diabetic rats. Increased β -hydroxybutyrate production was seen in diabetic rats; it was thought that a large fraction of butyrate evaded β -oxidation to acetyl-CoA and was converted directly into acetoacetyl-CoA. Different physiological states can therefore be monitored by *in vivo* ^{13}C MRS since labelling patterns following ^{13}C -enriched metabolite administration would be different.

In vivo ^{13}C MRS has also been applied to monitor the pharmacokinetics of ^{13}C -labelled xenobiotic products in hepatic metabolism. One such study used a phenacyl imidaolium compound that effects glycogen synthesis. It was shown that glycogen synthesis increases twofold in drug-treated rats and it was suggested that augmentation of the indirect pathway is the probable mechanism. Further studies have shown that long-term monitoring of drug concentrations is possible using ^{13}C -labelled compounds, which may be important for monitoring hepatic tumour treatments.

Muscle

Most human ^{13}C MRS studies in muscle have concentrated on the study of glycogen synthesis and its role in NIDDM, glycogen storage diseases and muscle myopathies. Studies of insulin action on muscle glycogen synthesis have shown that there appears to be an impairment of muscle's ability to either take up glucose or assimilate it as glycogen in NIDDM.

Studies have used *in vivo* ^{13}C MRS to study muscles following intense exercise. This, together with interleaved ^{31}P MRS, has provided important information on the phosphorylation states of glycogen synthase that could be correlated with post-exercise glycogen synthesis rates. Studies of this kind could provide important information on enzyme pathways that may be defective in particular muscle myopathies. Acetate metabolism has also been assessed in rabbit muscles to determine rates of anaplerotic flux (i.e. determination of label of glutamate and glutamine) compared with basal flux of the Krebs

cycle. Different muscle types (muscle fibre/oxidative or nonoxidative) have dissimilar anaplerotic flux rates, which may again be relevant for particular disease types.

Heart

In vivo ^{13}C MRS of the heart is difficult owing to continuous contraction of the heart. For this reason, together with the relative insensitivity of the ^{13}C nucleus, which requires a large number of averages, *in vivo* MRS studies are few. Consideration of the metabolites within blood must also be made so that the spectral acquisitions contain information purely reflecting heart metabolism. The bulk of studies on the heart have therefore been conducted using isolated, perfused organs. However, there have been a few *in vivo* studies that have looked at glycogen synthesis rates following infusions of acetate and glucose. These studies can provide information about physiological conditions that may effect carbohydrate utilization in favour of fatty acid metabolism, with implications for coronary heart disease.

Brain

In vivo ^{13}C MRS of the brain has been used to determine *in vivo* levels of glutamate, glutamine, γ -aminobutyrate (GABA), and lactate following intravenous infusions of enriched precursors. Brain tumours in rats have been studied to investigate carbohydrate metabolism following administration of $[1-^{13}\text{C}]\text{glucose}$. Rat gliomas produced lactate and glutamate/glutamine as well as glycogen. Further studies used combinations of labelled substrates such as glucose and acetate to determine the relative flux through the tricarboxylic acid cycle together with their relative conversion rates into the cerebral amino acids, important for neurotransmission. Both these studies suggested that *in vivo* ^{13}C MRS is ideal for studying the individual carbons of different metabolites in the brain. Furthermore, cerebral compartmentation of glial and neuronal cells may also be studied because of their

different metabolism. Two separate glutamate pools and two separate tricarboxylic acid cycles, one preferentially metabolizing acetate and the other mainly using unlabelled acetyl-CoA and a predominant production of GABA in the glutamate pool lacking glutamine synthase, have been identified, accounted for by either the glial or neuronal cells.

A further application of *in vivo* ^{13}C MRS has been to study the metabolite changes associated with mild or severe hypoxia as well as electroshock. Changes associated with lactate and the cerebral amino acids were correlated with both electroshock and degree of hypoxia. This work may be useful in characterizing the metabolic state following epilepsy, stroke, trauma, tumours and other pathological conditions in humans. In humans, total brain glutamate concentration has been assessed following $[1-^{13}\text{C}]$ glucose infusions, while in stroke it has helped to determine metabolic turnover. Some of these studies will benefit from the introduction of proton-observed carbon-edited (POCE) techniques, which can provide better relative sensitivity and resolution. This technique has been very useful, for example, in determining the effects on brain metabolism of drugs such as inhibitors of succinate dehydrogenase and the GABA-transaminase inhibitor vigabatrin.

Application of *In Vivo* ^{13}C MRS to lipids

The main application of *in vivo* ^{13}C MRS to the field of lipids has been the study of adipose tissue composition. Although the natural abundance of the ^{13}C isotope is low, the high content of lipids in adipose tissue has enabled acquisition of ^{13}C MR spectra *in vivo* in a matter of minutes, with or without proton decoupling. This has allowed the use of this technique on subjects (e.g. neonates and in pregnancy) where power deposition from decoupling, though small, is still unacceptable.

Adipose tissue

Adipose tissue is principally composed of triglycerides and it has been shown to play an important role in major diseases, including NIDDM and cardiovascular disease. Preliminary studies in the early 1980s showed that *in vivo* ^{13}C MRS could be used to detect differences in the lipid composition of adipose tissue and liver in rats fed a diet high in polyunsaturated fatty acids. The first human studies showed that linoleic acid ($18:2n-6$), usually the principal polyunsaturated fatty acid present in human adipose tissue, dominated the polyunsaturated signal observed *in vivo*, allowing estimation of this stored essential fatty acid. Further work showed that fatty acid composition of adipose tissue closely correlated with dietary fat content, with subjects on long-term vegan diet showing significantly higher levels of polyunsaturated

fatty acids and reduced saturated fatty acids compared to omnivores (general public) and vegetarians. Indeed, there was no difference in the adipose tissue composition of vegetarians compared to omnivores, suggesting that the former have substituted the animal fat (mainly saturated) with saturated fat in dairy products.

In vivo ^{13}C MRS has also been used to study adipose tissue composition in babies. The work showed that the influence of maternal diet on infant adipose tissue composition and changes due to gestational age and during postnatal development could all be detected noninvasively by *in vivo* ^{13}C MRS. Preterm infants had significantly lower levels of unsaturated adipose tissue fatty acids than the infants born at full term. Furthermore, the level of unsaturated fatty acids continued to increase as the infants matured (from birth to 6 weeks, to 6 months). Interestingly, the authors also found that infants breast-fed by vegan mothers had 70% more polyunsaturated fatty acids than infants breast-fed by omnivore mothers, the long-term consequences of which (beneficial or harmful) are unknown. The same authors showed that *in vivo* ^{13}C MRS could also measure the effect of intensive exercise on adipose tissue composition of adult human volunteers. A decrease in polyunsaturated fatty acids was observed, suggesting that exercise is an independent factor for adipose tissue composition.

In addition, *in vivo* ^{13}C MRS has been applied to the study of adipose tissue composition in disease. Children with cystic fibrosis were shown to have lower levels of polyunsaturated adipose tissue fatty acids than healthy children, possibly owing to a disorder in essential fatty acid metabolism that may be partly responsible for the development of the disease. Further studies with *in vivo* ^{13}C MRS in disease have shown a significant increase in saturated adipose tissue fatty acids following transplantation and subsequent weight gain in malnourished patients with liver cirrhosis. It was suggested that this increase in saturated fatty acids may be secondary to a general repletion of membrane polyunsaturated fatty acids or the use of essential fatty acids for biosynthesis of eicosanoids in the post-operative period.

Liver

^{13}C MRS has also been used for noninvasive quantification of hepatic triglyceride content. Diagnosis of hepatic steatosis (fatty liver) is important because this is a reversible condition and early detection can help to prevent irreversible liver damage. The condition is normally diagnosed by a liver biopsy, but the invasive nature of this procedure and the problems associated with biopsies make it difficult to monitor patients at risk of developing hepatic steatosis. In a study of 15 patients with varying degrees of fatty infiltration it was shown that by quantifying the intensity of the CH_2 resonances from the *in vivo* ^{13}C MR spectrum of the liver it was possible to

determine hepatic lipid content. Excellent correlation with conventional liver biopsy measurements was observed. As the authors suggested, this technique will in future become a valuable tool in the diagnosis and follow-up in patients with hepatic steatosis.

Brain

The application of *in vivo* ^{13}C MRS to the study of brain lipids has been rather limited, partly because most of the lipids in the brain are present in the form of membranes. This gives rise to broad and uninformative signals. An interesting possibility for improving the discriminatory power of MRS, as applied to lipids, is the use of ^{13}C -enriched fatty acids. However, at present such studies would be prohibitively expensive as the subjects would be required to consume gram quantities of ^{13}C -enriched fatty acid.

In Vivo ^{19}F MRS

Fluorine-19 is a highly NMR-sensitive and naturally abundant nucleus. An important advantage of ^{19}F MRS is the fact that it allows direct observation of fluorinated compounds and their metabolites in the human body without background signal from tissue. *In vivo* ^{19}F MRS has been used to detect noninvasively anticancer and psychoactive drugs and other fluorinated compounds and to study their metabolism. It has also been used to monitor the effects of anaesthetics and to measure intracellular pH and calcium levels.

One of the major applications of *in vivo* ^{19}F MRS has been in the field on oncology, detecting and monitoring the metabolism of fluorine-containing anticancer drugs. An important chemotherapeutic compound is the fluorinated drug 5-fluorouracil (5-FU). Much of the work with ^{19}F MRS has concentrated on determining optimal drug administration schedules and studying the effects of this drug on both tumour and healthy tissue. ^{19}F MRS has allowed detection and serial measurement of 5-FU and its metabolites in patients undergoing chemotherapy, increasing the understanding of the variation in efficacy of chemotherapy in different subjects (Figure 2). For example, levels of 5-FU 'trapping' by tumours following intravenous administration of the drug have been measured. The results reveal that patients whose tumours trapped the drug had a significantly better response to chemotherapy than those patients whose tumours did not trap 5-FU. This differential in response to therapy could not be ascertained from the standard plasma concentration measurements. From this study it was concluded that ^{19}F MRS can be used to identify patients who are likely to respond to chemotherapy with 5-FU and can therefore aid selection of the optimal treatment for individual patients. Studies of 5-FU metabolism in patients

Figure 2 (a) Liver *in vivo* ^{19}F MR spectrum at 60 MHz following administration of 5-fluorouracil (5-FU). (b) Time course of 5-FU and its major catabolite α -fluoro- β -alanine (FBAL). (FUranuc = 5-fluorouracil nucleoside + nucleotides). Reproduced with permission from Semmler W, Bacher-Baumann P and Guckel F (1990) Real time follow-up of 5-fluorouracil metabolism in the liver of tumor patients by means of F-19 MR spectroscopy. *Radiology* 174: 141–145.

with protein calorie malnutrition (a common condition in patients with cancer) have shown increased toxicity from this drug. Therefore, identifying alterations in 5-FU metabolism may be an important tool in reducing toxicity during chemotherapy. Interestingly, like ^{31}P MRS, *in vivo* ^{19}F MRS may also be used to measure pH non-invasively. This may be useful for ^{19}F MRS studies of tumours, as the uptake and retention of 5-fluorouracil is dependent on tumour pH.

An important area of research using *in vivo* ^{19}F MRS has been the study of the pharmacokinetics of fluvoxamine and fluoxetine, drugs used to treat obsessive-compulsive disorder and depression, respectively. Several groups have shown that it is possible to detect these compounds noninvasively in the brain. Brain fluvoxamine levels were shown to reach a steady state 30 days after consistent daily dosing, substantially more rapidly than reported for fluoxetine, which was shown to plateau after 6–8 months of treatment. Brain concentrations of both drugs were shown to correlate with plasma levels, though the absolute concentrations were substantially higher in

the brain. Comparison of the *in vivo* measurement of fluoxetine with *in vitro* samples taken at autopsy suggests that fluorinated drugs may not be 100% visible *in vivo*. These are based on the *in vitro* findings from just one brain that had been fixed in formaldehyde, so further studies would be required to confirm these findings.

Some of the other applications of *in vivo* ^{19}F MRS to the study of fluorinated drugs have included the study of fluorinated antibiotics and antifungal agents in animals and humans. Orally administered fleroxacin (a fluoroquinolone antibiotic agent) could be detected in the liver and calf muscle by *in vivo* ^{19}F MRS. Furthermore, its washout and metabolism were studied over a 24-h period. There are important implications of this work, and it will in future be possible to ensure that drugs reach their target site in appropriate concentrations.

In vivo ^{19}F MRS has also been used to study the pharmacokinetics and metabolism of anaesthetic agents such as halothane, isoflurane and desflurane in experimental animals. It has also been shown that anaesthetic agents can be observed noninvasively in the brains of patients immediately following surgery. The principal aim of these studies was to elucidate the mechanism of action of these compounds and eventually help in the development of more effective and selective anaesthetics. Unfortunately, factors such as sensitivity and localization of the region of interest (which are particularly relevant to the study of anaesthetics) have greatly limited the impact of this research.

Animal studies have shown that *in vivo* ^{19}F MRS can be used in metabolic studies. It has been shown that 3-fluoro-3-deoxy-D-glucose in the brain is metabolized primarily in the aldose reductase sorbitol pathway, suggesting that ^{19}F MRS may be a useful tool for the further elucidation of this pathway. Further studies have shown that it is also possible to study the metabolism of fluorinated galactose, tryptophan and protein *in vivo* and determine intracellular calcium levels. The concentration of this cation was shown to be the same in the kidney, spleen and brain of rats, at approximately 200 nM. These measurements were obtained by infusing the calcium indicator 5F-BAPTA (= 5,5-difluoro-1,2-bis(*o*-amino-phenoxy)ethane-*N,N,N',N'*-tetraacetic acid) intravenously or intraventricularly into the animal, and so the potential application to human subjects appears limited.

It has also been possible to follow the time course of recovery from nerve injury in skeletal muscle using *in vivo* ^{19}F MRS. Muscle injury leads to significant decreases in the energy state and local circulation dynamics, which appear to reverse during recovery. While ^{31}P MRS was used to determine the energy status of the cells, ^{19}F MRS was utilized to determine local circulation dynamics by measuring blood volume. The results indicate that the recovery processes of circulation precede those of energy state.

Many of the above studies have shown that in the future ^{19}F MRS is likely to become a valuable tool for monitoring drug metabolism at the site of action, though at the moment this is limited by the availability of *in vivo* MR scanners with ^{19}F capabilities.

Less Common Nuclei

Over the past decade or so there has been a significant increase in the number of 'less common' nuclei that are being utilized for *in vivo* MRS (see **Table 1**). The use of some of these nuclei was initially limited by technical constraints and/or inherent NMR characteristics. However, recent studies have shown that these nuclei can be used to increase our understanding of some important physiological processes.

A number of studies have utilized *in vivo* MRS to assess the extent of delivery of pharmacological substances to target tissue. Nitrogen-15 MRS in combination with intravenous $^{15}\text{NH}_4^+$ infusion into animal models of hepatic encephalopathy (**Figure 3**) enabled the determination of glutamine synthetase activity *in vivo*. The results show that *in situ* the activity of this enzyme is kinetically limited by the levels of some substrates and cofactors, and that the activity of phosphate-activated glutaminase was maintained at a low level by a sub-optimal concentration of P_i and the strong inhibitory effect of glutamine. The introduction of the heteronuclear multiple quantum coherence (HMQC) transfer technique is likely to further these studies by probing the kinetics of glutamine synthesis at physiological concentrations.

Similarly, lithium-7 MRS has been used to examine the pharmacokinetics of lithium, a drug that is widely used in the treatment of a number of psychiatric disorders. Initial studies showed that there was a slow accumulation of lithium in the brain, which may be responsible for the delay in therapeutic response that is often seen following the initiation of therapy. Subsequent studies showed that lithium levels in the brain and muscle were lower than the average serum concentration. From the ratio of these *in vivo* measurements, the authors hypothesized that the minimal effective concentration of brain lithium level for maintenance treatment of bipolar disorder could be determined. However, in a similar study, researchers found that in a subgroup of patients there was only a weak correlation between serum and brain lithium levels, which may account for the failure of lithium therapy in some patients with serum lithium levels within the therapeutic range. This suggests that measurement of *in vivo* brain lithium concentration by MRS may be more clinically relevant than simply assessing serum concentration.

Figure 3 *In vivo* ¹⁵N spectra at 24.3 MHz from cerebral region of (a) a control rat given low-rate ¹⁵NH₄⁺ infusion, showing cerebral [γ-¹⁵N]glutamine at a near physiological concentration; (b) a portacaval-shunt rat showing cerebral and blood ¹⁵NH₄⁺, in addition to [γ-¹⁵N]glutamine; (c) a control rat showing cerebral and blood [¹⁵N]urea and lower [γ-¹⁵N]glutamine. Peaks are downgoing following NMR convention for ¹⁵N spectroscopy. Reproduced with permission from Kanamori K, Parivar F and Ross BD (1993) A ¹⁵N NMR study of *in vivo* cerebral glutamine synthesis in hyperammonemic rats. *NMR in Biomedicine* 6: 21–26.

Boron-11 MRS has been used to assess the delivery of boron neutron capture therapy (BNCT) agents to a target lesion. Uptake and retention of these compounds was determined *in vivo* in humans and animals and the results show that there is differential retention between normal and abnormal tissue. Furthermore, ¹H-observed ¹⁰B-edited MRS has been shown to provide much higher sensitivity and could be utilized to monitor the distribution and excretion of boron agents noninvasively in patients about to undergo BNCT.

Sodium-23 MRS has been used to yield information on electrolyte balance, which appears to reflect physiological changes associated with cell function. In myotonic dystrophy, an inherited multisystem disease that leads to muscle malfunction, ²³Na MRS was shown to be a sensitive method for quantification of disease progression. Quantification of intracellular and extracellular sodium by MRS has also generated important information on organ function following transplantation or injury. In heart transplantation experiments in rats, ²³Na MRS showed that there was a steady increase in intracellular sodium 3 days prior to rejection, followed by a sharp

increase after rejection. In the liver, intracellular sodium levels were shown to be a sensitive indicator of hepatic dysfunction after major systemic injury. In the kidney, sodium compartmentation (intracellular, vascular and intraluminal) was determined using the shift reagent TmDOTP5, while in the brain this shift reagent was shown to be a useful tool in determining compartmental sodium concentration and measuring blood flow kinetics.

The activity of ion transport systems, such as sodium- and potassium-activated adenosine triphosphatase, has been studied *in vivo* by the use of ⁸⁷Rb MRS. This has been possible because rubidium has been shown to substitute for potassium in a number of transmembrane transport systems, accumulating in the intracellular space. Standard *in vitro* methods of determining Na⁺/K⁺-ATPase activity, which also use rubidium, give highly variable measurements and in some cases contradictory results. Many of these problems appear to have been overcome by the use of *in vivo* ⁸⁷Rb MRS, especially when sequential measurements are required. In a longitudinal study of spontaneously hypertensive rats, ⁸⁷Rb MRS showed that skeletal muscle rubidium rose at a faster rate in hypertensive rats than in control animals, which is consistent with a marked increase in Na⁺/K⁺-ATPase activity. This type of experiment emphasizes the value of *in vivo* MRS since rubidium kinetics can be determined sequentially on the same animal, minimizing inter/intra-subject variability as well as the number of animals required in the study.

In vivo deuterium (²H) MRS has been used to characterize amino acid metabolism, body iron content, brain and kidney metabolism and body fat utilization rates in rodents. These studies rely on the use of deuterium labelling or the existence of natural-abundance deuterium in water or lipids. For example, deuterium-labelled methionine was used to confirm the dominant contribution of the glycine/sarcosine shuttle to the metabolism of excess methionine, while deuterium-labelled glucose was used to show that systemic glucose level influences brain metabolic recovery following partial ischaemia. The renal distribution and metabolism of methyl groups was assessed by the use of deuterium-labelled choline. The results show that the concentration of trimethylamines, metabolic products of choline, was higher in the cortex and inner medulla than in the outer medulla, but that the inner medullary fraction was more liable to diuresis.

By combining D₂O dilution techniques with ²H MRS it has been possible to study fat turnover *in vivo*. The rate of loss of deuterium from body fat, after a short period of D₂O administration, has been shown to reflect utilization of body fat. This technique was used successfully to demonstrate that induction of diabetes in mice did not affect the utilization of fat as a metabolic fuel. Given that D₂O administration is regularly used with human subjects, this opens up the possibility, for the first time, of

determining fat turnover noninvasively in human subjects.

A number of studies have used nuclei such as oxygen-17, aluminium-27 and xenon-129 in conjunction with *in vivo* MRS for structural or dynamic measurements in different organs. ^{129}Xe signals were detected in the lung and head from human volunteers following inhalation of hyperpolarized ^{129}Xe gas, allowing the determination of the temporal evolution of the gas-phase and dissolved-phase components. Most of this work, however, was used to demonstrate the feasibility of obtaining xenon images of the lung. ^{129}Xe imaging now allows the possibility of imaging the lung at resolution equivalent to that of conventional imaging of normal tissue. ^{27}Al MRS has been applied to the visualization of gastric emptying and measurement of gastric phospholipids, while ^{17}O MRS has been used to explore cerebral blood flow. Although these studies have again concentrated mainly on their technical feasibility, they do open up important areas of clinical and biochemical research.

Conclusions

The application of *in vivo* multinuclear MRS to biological sciences is an ever-expanding area of research. Present-day clinical NMR systems routinely allow the use of ^1H and ^{31}P MRS in clinical and scientific research; however, the use of other nuclei is still restricted to a relatively small number of research groups around the world. This is principally for commercial reasons rather than scientific or technical considerations. Demands for an increase in the multinuclear capability of commercial systems is of course increasing as the usefulness of nuclei such as ^{13}C , ^{19}F and ^{15}N continues to be demonstrated both in animal models and in human subjects. It is conceivable that in the near future these technical capabilities will be routinely available in most clinical systems as they are today available in most *in vivo* animal systems. This will no doubt greatly help to further elucidate metabolic mechanisms in health and disease and in the development and monitoring of the efficacy of novel clinical treatments, including gene therapy.

Introduction

Nuclear magnetic resonance (NMR) spectroscopy is arguably one of the most versatile techniques in use in biomedical research today. Discovered in the 1940s, NMR was initially used in physics to measure nuclear magnetic moments. During the next 20 years or so, applications of NMR developed rapidly and soon it became an invaluable tool for chemical analysis with the discovery of the chemical shift and spin–spin coupling. The use of NMR to study molecular structures, including proteins and other biological molecules, was boosted in the late 1960s with the development of superconducting magnets that provided high magnetic fields and the implementation of Fourier transform (FT) NMR. However, it was not until the mid-1970s that the first applications of NMR in studies of living biological systems were reported. After it was realized that one could get reasonably resolved NMR spectra (initially using ^{31}P NMR) from living tissue, the interest in *in vivo* NMR spectroscopy grew rapidly and soon investigations of living animals and humans followed. Nowadays, many applications of *in vivo* NMR spectroscopy are in the area of clinical medicine, and by analogy to magnetic resonance imaging (MRI), where “nuclear” was dropped from the acronym to remove any negative connotation, *in vivo* NMR is simply referred to as *in vivo* magnetic resonance spectroscopy (MRS).

Currently, MRS is being used in a wide range of studies of biological processes in systems as diverse as a single cell, isolated perfused organs, and living animals and humans. It is also possible to combine MRS with different NMR-based methods, particularly magnetic

resonance imaging (MRI), to acquire anatomic, metabolic, physiological, and functional information from the same experiment, providing uniquely multivariate information. The aim of this article is to provide an overview of the MRS methods for *in vivo* studies and demonstrate the potential utility of MRS in biomedical and clinical research.

Technical Aspects

Chemical Shift

In vivo MRS utilizes the principal NMR phenomenon that nuclei in different chemical groups resonate at slightly different frequencies, an effect referred to as the chemical shift. An algorithm called Fourier analysis is usually used to work out the frequencies of the signal, generating a spectrum. By placing a sample in a magnetic field and generating a signal following RF excitation, the chemical content and structure of the sample can thus be determined noninvasively and non-destructively. For example, a typical spectrum of hydrogen (^1H) MRS of the human brain exhibits characteristic resonances of several cerebral metabolites, including among others N-acetyl aspartate (NAA), a putative marker of neurons and their processes, and moieties containing choline (Cho) and creatine (Cr), as shown in **Figure 1**. Consequently, ^1H MRS of the human brain has become a powerful tool to study brain disorders that involve damage or loss of neurons, such as Alzheimer’s disease as well as staging of brain tumors. An important issue to note in the context of *in vivo* MRS is that detectable resonance lines are primarily from small freely moving molecules, whereas large or relatively immobile molecules, such as phospholipids and proteins, tend to result in very broad resonance lines that usually disappear in the spectral baseline. Similar to traditional NMR, *in vivo* MRS generally benefits from a higher magnetic field through a combination of greater sensitivity and increased chemical shift dispersion, as shown in **Figure 1**, depicting ^1H MRS brain spectra from humans at 1.5 and 4.0 T and from a dog at 9.4 T. However, the benefits of a higher magnetic field can be much harder to achieve *in vivo*, because it needs to be considered that paramagnetic ‘impurities’ of tissue, that is, blood vessels and iron-storing proteins, can induce broadening of the resonance lines as magnetic field strengths increase. Nowadays, 3-T scanners with commercial packages for ^1H MRS are

Figure 1 Increases in spectral resolution of *in vivo* hydrogen (^1H) MRS data with magnetic field strength, showing data collected in human brain at 1.5 and 4.0 T and in dog brain at 9.4 T. Note the decrease in line width (in ppm terms) of the resonances of NAA, Cr, and Cho, which is unequivocal evidence for increased spectral resolution *in vivo*. Note: Arbitrary scale. Reproduced from Gruetter, et al. (1998). *Journal of Magnetic Resonance* 135: 260–264, with permission from Elsevier.

widely available for clinical studies in humans and the number of 7-T scanners for humans offering MRS capabilities is steadily increasing worldwide. For small animal studies, 10-T magnets are increasingly becoming the norm.

Water Suppression and Spectral Filtering

A major difficulty encountered in *in vivo* MRS is the spectral dominance of resonances from highly abundant cellular constituents, such as water and lipids. In biological tissue, water has a very high concentration of about 55 mol l^{-1} , exceeding the concentration of most metabolites sensitive to MRS, which are roughly in the 1.0 mmol l^{-1} range or slightly below, by almost five orders of magnitude. Avoiding water contamination of *in vivo* ^1H MRS has been a major technical objective for many years and the technical refinements are still ongoing. Initial concepts of water suppression have focused on the difference in chemical shift between the resonances of water and metabolites. One widely used method, appropriately coined CHESS for chemical shift selective suppression,

applies a series of narrowband radio frequency pulses to selectively saturate the water signal, followed by magnetic field gradients to destroy the coherence of any residual signal before the regular acquisition of metabolite signals begins. However, a fundamental limitation of this approach is the return of excited water toward magnetic equilibrium at which point water suppression is no longer effective. An alternative concept has therefore focused on carefully avoiding water excitation all together while exciting only the metabolites. This has been accomplished by the design of binominal radio frequency pulses that provide a good excitation profile over a wide range with the exception of a notch at the center frequency, that is, at the resonance of water, which is left unperturbed.

To date, the concept of water suppression (or conversely, non-excitation) has evolved to more general spectral editing techniques far beyond the mere elimination of solvent resonances. In general, spectral editing aims at the unambiguous identification and quantification of metabolite resonances in regions of spectral overlap. For example, multiple quantum filter (MQF) editing techniques exploit magnetic differences between hydrogen nuclei that are in close proximity to each other to impose an additional weak magnetic field on each other (so called coupled) and hydrogen nuclei that are isolated (uncoupled). The ability of MQF to differentiate between coupled and uncoupled nuclei can be used as a means of clarifying spectral complexity in *in vivo* MRS. One representative application of MQF is the selective detection of GABA (4-aminobutyric acid), the major inhibitory neurotransmitter in the mammalian brain. Conventional ^1H MRS of GABA is fraught with difficulties due to its low concentration and significant spectral overlap with resonances from other metabolites, especially the methyl group of Cr. Fortunately, the nuclei of GABA are coupled whereas those of the methyl group of Cr are not, which provides the context for the design of an MQF experiment that selectively retains the GABA resonances while suppressing most background resonances, as illustrated in **Figure 2**. Analogous techniques have been applied to heteronuclear editing, especially with the use of magnetic labels such as carbon (^{13}C) MRS.

Spatial Localization and Spectroscopic Imaging

To obtain high-resolution MR spectra *in vivo*, for example, from a human brain, it is necessary to localize MRS measurements to a particular region of interest. Without localization, MR spectra not only lack anatomical specificity but are usually also severely distorted due to large-scale magnetic susceptibility effects, such as from tissue/air/bone interfaces. There are principally two different approaches for localization. In one approach, a small radio frequency coil for excitation and reception of the NMR signal is placed on the surface of

Figure 2 (a) Conventional *in vivo* ^1H MRS of human brain, showing the prominent resonances of cerebral N-acetyl aspartate (NAA) and that of the moieties of choline (Cho) and creatine (Cr). (b) Metabolite null spectrum using the same acquisition and processing parameters than in (a) to demonstrate the spectral baseline. (c) *In vivo* GABA spectrum from the same brain region after multiple quantum filter (MQF) spectral editing. (d) Metabolite null spectrum using the same acquisition and processing parameters than in (c) to demonstrate the spectral baseline after MQP spectral editing. The vertical scales used in (a)–(d) are the same. Note: Arbitrary scale. Reproduced from Shen, et al. (2002) *Magnetic Resonance in Medicine* 47: 447–454, with permission from Wiley-Liss.

the subject inside the magnet. Localization is then achieved by the placement and size of the coil as well as by the power of the radio frequency pulses that determines the depth of the excited region. However, spatial localization provided by this arrangement is relatively ill defined, and therefore improved spatial localization techniques (in particular, definition of localization in all three dimensions) are desirable. In the other approach, three band-limited radio frequency pulses, augmented by magnetic field gradients (in analogy to slice-selective MRI), are applied to excite three mutually orthogonal planes and arranged so that only the signal originating from the planes intersect (the single voxel) survives. *In vivo* MRS with single-voxel techniques has become popular in clinical practice, because the approach is widely available and yields usually well-resolved spectra. However, the main drawback of single-voxel MRS is the inability to determine the spatial heterogeneity of spectral patterns (which is often important in tumors or brain

Figure 3 Brain metabolite images of NAA, glutamine and glutamate (Glx), choline (Cr), creatine (Cr), and myo-inositol (myo-Ins) together with the corresponding anatomical MRI (T1-weighted). Reproduced from Soher, et al. (2000) *Magnetic Resonance Imaging* 18: 1159–1165, with permission from Elsevier.

lesions for instance), and repetitions of single-voxel MRS at multiple locations is unbearably ineffective for collecting spatial information. This can be overcome with MRS imaging (MRSI), which imposes on each of the spectral readouts phase-encoding information in one direction by augmenting MRS by a short magnetic field gradient, analogous to the phase-encoding gradients in MRI. This yields metabolite maps, as those shown for human brain in **Figure 3**, providing a wealth of complementary information to structural MRI for example. However, the scan time of MRSI is considerably longer than that with single-voxel MRS, which may limit its use in clinical practice, although in terms of sensitivity per time, MRSI fares much better than single-voxel MRS. New technical advancements have been exploited in recent years to reduce the scan time of MRSI, borrowing from developments of accelerated MRI, and therefore scan times on the order of a few minutes for MRSI are no longer uncommon.

Sensitivity Enhancement

Several different NMR-sensitive nuclei can be used in the study of biological systems, and the most common are ^1H , ^{13}C , ^{31}P , and ^{19}F . Compared to ^1H , the other NMR nuclei provide substantially less signal and consequently, sensitivity is for most of them even a greater challenge than for ^1H MRS. This is particularly true for *in vivo* ^{13}C MRS, where a low signal intensity from low metabolite

Figure 4 Color-coded images of computed uptake of hyperpolarized ^{13}C in a rat tumor, simultaneously for pyruvate, lactate, and alanine. The metabolite images are projected on the anatomical ^1H MRI. Alanine is most prominent in the skeletal muscle around the spinal cord, whereas the tumor tissue is indicated by the highest signal for lactate. Note the different color scales. Reproduced from Golman et al. (2006) *Cancer Research* 66: 10855–10860, with permission from the American Association for Cancer Research.

concentrations is aggravated by the fact that only a small fraction (ca. 1%) of the carbon nuclei are magnetic (^{12}C does not give NMR signals) and contribute to the signal when placed into a magnetic field. In addition, ^{13}C nuclei have a small gyromagnetic ratio that is only a quarter of that of ^1H . Despite such obstacles, there has always been a huge interest in ^{13}C MRS, because carbon is the backbone of organic compounds. Another advantage of ^{13}C MRS is the large chemical shift range for carbon (about 250 ppm compared with roughly 10 ppm for ^1H), allowing the resolution of certain metabolites in tissue that cannot be resolved by ^1H MRS. NMR strategies to enhance the ^{13}C -signal have therefore particularly high interest for ^{13}C MRS.

One way to enhance the sensitivity of ^{13}C MRS is by using ^1H decoupling. Without ^1H decoupling, ^{13}C resonances are split and their spectral intensity is accordingly diminished. With ^1H decoupling, the J-coupled multiplet peaks of the ^{13}C resonances fuse into single lines and the overall intensity increases, which can be significant. ^1H decoupling is achieved by transmitting radio frequency pulse trains to selectively manipulate the weak magnetic field that ^{13}C and ^1H impose on each other. A major practical limitation of ^1H decoupling is an increase in deposition of radio frequency energy, which can heat up tissue to potentially damaging levels. Another way to enhance the sensitivity of ^{13}C MRS is to chemically introduce ^{13}C labels into a metabolic substrate, such as ^{13}C -labeled glucose, and after administration, monitor the uptake of the ^{13}C -label with or without any interfering background signal. This strategy has been extensively used to study noninvasively the time course of specific activity of glucose *in vivo*. The findings demonstrated that ^{13}C MRS allows one to simultaneously assess glucose consumption and exchange across the mitochondrial membrane in the human brain. Recently, dramatic enhancement of the ^{13}C -signal in excess of 10,000 times has been achieved with two novel methods of hyperpolarizing the ^{13}C nucleus. One method is based on dynamic nuclear polarization (DNP) and the

other on para-hydrogen allowing dramatically enhanced nuclear alignment, coined PASADENA. Both have the potential to totally change the clinical use of ^{13}C -labeled MRS. Dramatic signal enhancements have been demonstrated *in vivo* with ^{13}C -labeled pyruvate, a molecule that is at the cross-roads for energy delivery inside the cell and thus, particularly suitable to study fundamental energy properties, such as in tumors. The strongly enhanced ^{13}C -signal generated by the hyperpolarized ^{13}C -pyruvate allowed mapping of the pyruvate, lactate, and alanine transformations in rats with implanted tumors, as shown in **Figure 4**. The ability to increase the NMR signal of ^{13}C -labeled biologically relevant metabolic substrates by several orders of magnitude promises to provide new methods for measuring and understanding tumor metabolism *in vivo*.

Applications

^1H MRS

^1H MRS of the brain gives useful information on a number of different neurological and psychiatric disorders. For example, in Alzheimer's disease, ^1H MRS studies have consistently found reduced NAA, consistent with neuron loss, as well as elevated myo-inositol (a proposed marker of glia), potentially reflecting increased gliosis secondary to neuron loss. Interestingly, similar abnormalities in brain ^1H MRS were already seen in mild cognitive impairment, a syndrome that is thought to be a transitional stage to Alzheimer's disease. ^1H MRS may therefore have potential as an early marker of Alzheimer's disease. Other applications of ^1H MRS at present are in demyelinating diseases, including multiple sclerosis, as well as in epilepsy, infection, inborn errors of metabolism, traumatic brain injury, and assessment of brain tumors. As the detection limits of ^1H MRS are being extended at increasingly higher magnetic fields, future work may result in detection of smaller resonances arising from lower-concentration metabolites.

¹³C MRS

¹³C MRS has been used to investigate glycogen metabolism in liver, heart, and muscle. The appearance of ¹³C-labeling in glutamate from ¹³C-labeled glucose has been used as an index of oxidative metabolism and flux through the tricarboxylic acid (TCA) cycle in a variety of studies of brain and heart. Using optimized administration of ¹³C-labeled glucose, the time course of ¹³C-enrichment of glutamate has been used to non-invasively determine oxygen consumption *in vivo*. Similar studies have been performed to assess the synthesis of NAA in the human brain. Perhaps the most clinically advanced role of ¹³C MRS has been noninvasive assessment of prostate cancer.

³¹P MRS

³¹P MRS has been used to assess bioenergetics of the human brain, heart, and muscle. The isolated perfused heart was one of the first biological systems to be studied in detail using ³¹P NMR spectroscopy. Information provided by ³¹P MRS includes factors such as phosphocreatine and adenosine triphosphate concentrations and their ratio. The chemical shift of inorganic phosphate is pH dependent and is thus a marker of intracellular pH. Concentration of phosphodiesteres and phosphomonoesters can be measured. At 7 T, the larger chemical shift dispersion considerably reduces spectral overlap in ³¹P MRS, allowing the measurement of phosphoesters with greater precision.

¹⁹F MRS

In vivo ¹⁹F MRS can be a very useful technique for monitoring the distribution of fluorinated drugs and their metabolites. These include the PET agent 2-fluoro-2-deoxyglucose, and the study of its 3-fluoro-isomer as a probe of aldose reductase activity in brain. ¹⁹F MRS has also been used to measure the elimination of fluorinated anesthetics from the brain and the metabolism of halothane in the liver.

Works-in-Progress

In vivo MRS will likely continue to benefit from the development of stronger NMR magnets and better radio frequency coils. For example, a 21-T magnet with a bore of 105 mm (about 4 in.) suitable to study small living animals has been built. Building an 11-T magnet for humans is being considered. Paralleling the development of magnets, new designs of radio frequency coils for excitation and signal reception are under development, promising improvements in sensitivity and speed for MR spectroscopy and imaging. However, the technical challenges of *in vivo* MRS, such as tissue heating, are also mounting with increasing field strength. Furthermore, some spectral patterns that are not governed by chemical shift but dominated by spin-spin interaction do not directly benefit from higher magnetic fields. Here, possible improvements for simplifying *in vivo* MRS data are spectral editing and the use of two-dimensional spectroscopy. Potentially, the largest expansion for *in vivo* MRS is the use of hyperpolarized ¹³C labels. These may become a useful tool for rapid *in vivo* identification of tumors and lesions, providing novel biomarkers.

Introduction

The phosphorus nucleus has occupied centre stage in the development of *in vivo* NMR spectroscopy for two important reasons. First, the NMR properties of the nucleus are well suited to *in vivo* NMR (100% natural abundance, reasonable sensitivity and adequate but not excessive chemical shift). Second, key metabolites, particularly those involved in the production of energy, contain phosphorus and are present in substantial concentrations in living tissue. It is for these reasons that the first NMR spectra of living cells (a suspension of erythrocytes), and later of excised frog muscle, were obtained using ^{31}P NMR. In both instances, resonances were observed from adenosine triphosphate (ATP) and inorganic phosphate, the position of the latter being an indicator of intracellular pH. Additional peaks were seen from 2, 3-diphosphoglycerate (2, 3-DPG) in red blood cells and creatine phosphate in skeletal muscle. Despite the comparative simplicity of ^{31}P NMR tissue spectra, the technique offers unique insight into the regulation of critical energetic pathways. The early studies of *ex vivo* samples were soon extended to *in vivo* examination of intact animals and later to humans, experiments which were made possible by the development of large superconducting magnets, the use of local surface coil probes and the invention of a variety of techniques for localizing the source of the NMR signal.

Techniques for ^{31}P Spectroscopy In Vivo

Signal Acquisition and Spatial Localization

Perhaps the most critical step in the development of *in vivo* spectroscopy was the realization that it was not necessary to surround the 'sample' with a conventional NMR probe, but that a small local coil (a surface coil)

could be placed against an animal to preferentially receive signals from the tissues adjacent to this coil. The surface coil has two advantages, namely excellent sensitivity close to the coil and inherent localizing properties owing to the rapid fall-off of the magnetic flux away from the coil. However, when deep tissues are to be investigated, additional localization is required. In choosing an appropriate technique for obtaining ^{31}P NMR spectra from a live animal or man, careful consideration must be given to the spatial resolution and signal-to-noise ratio which can reasonably be expected. As the phosphorus nucleus has only 6% of the sensitivity of the proton, it follows that these expectations will be somewhat more modest than for ^1H spectroscopy. The usual approach is to adopt the least demanding methodology appropriate for any particular application. As a consequence, in many instances simple surface coil localization is used to give adequate localization and provide the best signal-to-noise ratio in short acquisition times. When this simple approach is inadequate, a range of single and multiple voxel methods can be considered, but care must be taken to choose methods which work well at short echo times to avoid excessive T_2 relaxation and minimize problems due to the J modulation of peaks such as adenosine triphosphate.

Dealing first with the single voxel approach, image selected *in vivo* spectroscopy (ISIS) is frequently the method of choice because the spins are kept predominantly along the z axis, thus minimizing T_2 and J coupling effects. Other localizing schemes (e.g. stimulated echo acquisition mode spectroscopy (STEAM) and point resolved spectroscopy (PRESS)) which are commonly used for proton spectroscopy can give reasonable results, but are more sensitive to the aforementioned problems.

Where multivoxel localization is advantageous, chemical shift imaging techniques can be applied in one, two or three dimensions, but relatively poor spatial resolution is obtainable and long acquisition times are usually required.

Finally, it will often be advantageous to implement hybrid protocols in which, for example, two dimensions might be defined by an ISIS sequence, and phase encoded chemical shift imaging (CSI) implemented along the third axis, thus producing a set of spectra that represent slices through a well-defined column of tissue.

Proton Decoupling

The quality of *in vivo* ^{31}P spectra can be improved by the use of proton decoupling. Two benefits are available. Some of the phosphorus spectral lines are significantly broadened by scalar coupling to hydrogen. Irradiation of the protons during acquisition removes this interaction and sharpens the spectra. The effect is particularly advantageous in the phosphomonoester (PME) and phosphodiester (PDE) regions of the spectrum where conventional acquisition will fail to resolve, for example, glycerophosphocholine and glycerophosphoethanolamine. Together with the increased resolution, proton decoupling also increases the signal-to-noise ratio due to peak narrowing. A further increase in signal is available by low power decoupling during the interpulse relaxation period. Here, the nuclear Overhauser effect (NOE) can result in improved sensitivity of up to about 50% owing to interactions between the phosphorus nuclei and neighbouring protons.

Magnetisation Transfer

Under certain conditions, rates of chemical exchange can be measured using saturation- or inversion-transfer methods. These work by magnetically labelling one chemical species and observing the transfer of this magnetic signature to a second compound which is coupled by chemical exchange. For the technique to be viable, there needs to be significant exchange during a time scale which is of the order of the longitudinal relaxation time T_1 . Such reactions include the synthesis and hydrolysis of ATP (by measuring exchange between ATP and inorganic phosphate) and the fast exchange catalysed by the creatine kinase enzyme.

The *In Vivo* ^{31}P NMR Spectrum

Figure 1 shows spectra from human skeletal muscle, heart, liver and brain. Each contains the three peaks from ATP and one from inorganic phosphate. ATP shows three signals due to the different chemical environments of its three phosphorus atoms. These signals are further split by ^{31}P – ^{31}P J -coupling, but this splitting is not always detectable *in vivo* owing to the relatively broad lines. These peaks are normally designated 'ATP' but also contain minor contributions from other nucleotides, such as guanosine triphosphate, NADH, NADP, UDP-sugars and ADP. The signal which contains the least contamination from other compounds is the one from the central (beta) phosphate, which appears at the upfield end of the spectrum, and so this peak is generally used for the measurement of ATP levels. In addition, spectra from muscle, heart and brain contain a prominent peak from creatine phosphate (PCr). This compound is absent from liver. Liver and brain spectra also contain

Figure 1 ^{31}P spectra of human organs (a) calf muscle, (b) heart, (c) liver, (d) brain. Peak assignments: 1. PME, 2. P_i , 3. PDE, 4. PCr, 5. ATP, 6. 2, 3-DPG. substantial peaks designated as phosphomonoester (PME) and phosphodiester (PDE). These regions of the spectra can contain metabolites involved in membrane metabolism and also phosphorylated sugars involved in glycolysis. An important feature of the ^{31}P spectrum is that the position of the inorganic phosphate (P_i) peak is pH dependent, thus providing a sensitive marker of intracellular acidity/alkalinity.

Biological Relevance of the Peaks

Adenosine triphosphate (ATP)

ATP is the universal energy carrier in all cells. When energy is required for cell functions such as preserving ionic gradients, muscular contraction, etc., the terminal phosphate is cleaved by ATPase enzymes to form adenosine diphosphate (ADP) and inorganic phosphate, an energy-producing reaction:

ATP is resynthesized by one of several pathways, most usually by ATP synthesis using energy obtained from oxidative or anaerobic metabolism.

Inorganic phosphate (P_i)

This compound may be considered as the waste product of ATP hydrolysis or conversely as a substrate for ATP synthesis. It may also play a role in regulating the supply of energy via oxidative metabolism in the cells' mitochondria. At physiological pH, P_i exists in two ionic forms in fast equilibrium via the reaction:

This reaction has a $\text{p}K_a$ of 6.75, and so the relative concentrations of P_i^- and P_i^{2-} vary with the pH. Owing to

the fast exchange between these two species, the position of the P_i peak in the spectrum reflects the weighted average of the two chemical shifts, and is thus a direct measure of pH.

Creatine phosphate (PCr)

This molecule is present in abundance in muscle, heart and brain cells. Through the fast equilibrium reaction catalysed by creatine kinase, PCr buffers the ATP concentration by phosphorylating ADP, the reaction being:

PCr is depleted during sudden energetic demands such as vigorous muscle contraction.

Adenosine diphosphate (ADP)

ADP is a substrate for ATP production, and a product of its hydrolysis. ADP stimulates respiration (oxidative metabolism) – breakdown of ATP increases ADP which in turn activates the processes which provide energy for ATP synthesis. In tissues such as muscle, much of the ADP is bound to macromolecules and therefore invisible to NMR. However, the free (and therefore metabolically active) ADP, usually present in only micromolar concentrations, may be deduced using the creatine kinase equilibrium (see above).

Phosphomonoesters (PME)

Certain intermediaries in the glycolytic pathway such as glucose and fructose phosphates resonate in this region of the spectrum and are sometimes detected. More usually, the PME peak comprises the lipid precursors phosphocholine and phosphoethanolamine.

Phosphodiester (PDE)

This region also contains compounds involved in membrane metabolism, specifically glycerophosphocholine (GPC) and glycerophosphoethanolamine (GPE).

Broad resonances

In addition to the sharp peaks that have just been mentioned, there will often be underlying broad 'humps' in the phosphorus spectrum, arising from phosphorus moieties that are immobile or tumbling very slowly. Phospholipid head groups in cell membranes produce a broad and asymmetric signal centred under the PDE part of the spectrum. Bone also produces a broad resonance, several kilohertz wide, which is easily visible in surface coil spectra of the head, but is not usually present in localized spectra due to its very short T_2 .

Applications in Skeletal Muscle

Skeletal muscle is a tissue that is particularly suited to study by ^{31}P NMR. From a technical standpoint, muscle is an ideal target because it exists close to the body surface and is not obscured by any other pool of phosphorus-containing metabolites. From a biochemical standpoint, muscle is especially interesting because its energetic demands vary by at least two orders of magnitude (from rest to exercise) and so it provides an example of exquisite metabolic control which can be studied non-invasively. Finally, muscle can be stressed readily by exercise within the NMR instrument, thus facilitating the real-time investigation of the dynamics of energetic regulation.

Animal studies of skeletal muscle often employ direct stimulation of the sciatic nerve to induce contraction and associated metabolic response. Basic metabolic control can be investigated using such a model, as can a wide range of disease-related processes. Genetically abnormal animals provide models of diseases such as muscular dystrophy and ^{31}P NMR spectroscopy provides a tool for investigating metabolism, pH regulation and possible therapeutic interventions.

In a typical human examination, a subject will perform an exercise regime within the magnet, perhaps squeezing a handgrip or pressing down a loaded pedal. The NMR signals are usually collected using a surface coil placed over the exercising muscle and a series of spectra are collected to follow the metabolic state before, during and after the exercise. A typical time course is shown in **Figure 2**. The several metabolite concentrations and pH are then used to quantitatively assess the metabolic response to the stress, and, by using models of metabolic control, unique insight can be gained into the

Figure 2 A typical time course for changes in PCr and pH during exercise and recovery in the human forearm muscle.

complementary processes of mitochondrial respiration and anaerobic metabolism.

Muscle Metabolism

Figure 3 is a block diagram of the main energy-producing pathways in skeletal muscle (and other tissues, except that the creatine kinase pathways may not be present). In resting muscle, ATP is synthesized only by oxidative metabolism, but during exercise glycolysis (anaerobic metabolism) and PCr breakdown via the creatine kinase reaction provide additional ATP production. Although only three compounds are directly detected by ^{31}P NMR, others may be deduced by making assumptions based on data derived from biopsy analysis. In particular, an estimate of free [ADP] is obtained using assumed values of ATP and total creatine concentrations, and applying the known value for the creatine kinase equilibrium constant.

In using these data to investigate metabolic control *in vivo*, two periods within an exercise regime are of particular importance. At the start of exercise, energy is produced primarily by glycolysis and a breakdown of creatine phosphate. The latter is measured directly while the former produces lactate which is reflected in the pH. At the start of recovery, glycolysis stops, the energy demands fall dramatically and oxidative metabolism restores the PCr. Using models for proton efflux and metabolic control by ADP, it is possible to assess the relative contributions of the various energy pathways in both normal and diseased muscle.

Diseases of Skeletal Muscle

In man, the understanding and quantification of muscle energetics have facilitated the study and, sometimes, diagnosis of a wide range of muscle diseases. Often these stem from inherited genetic abnormalities, including the dystrophies, mitochondrial myopathies and so-called

energy storage diseases. Muscle can also be affected by arterial disease and systemic abnormalities secondary to, for example, renal and cardiac failure. Many studies have looked at these phenomena and monitored the response to training or therapeutic intervention.

Applications in the Heart

Basic NMR research of the heart has concentrated on studies of the organ *ex vivo* (the excised heart, perfused with physiological buffer, can be maintained in a viable and beating condition for many hours). *In vivo* studies in both animals and man are more difficult – the heart is a moving target, is filled with blood and overlaid with skeletal muscle which gives a similar ^{31}P NMR signature. The approaches that have been applied in animal systems often involve exposing the organ and suturing a surface coil to the heart wall, thus facilitating the measurement of localized metabolic events. In man, single voxel ISIS is sometimes used, or chemical shift imaging, usually as a hybrid experiment (see above) where spectra are obtained from parallel slabs of tissue. The biochemistry of the heart is in many ways similar to skeletal muscle. However, the dynamic range of energetic demand is less extreme than in muscle and in normal controls it is difficult to induce significant changes in the ^{31}P spectrum from the heart. In the diseased heart, the main findings have been that cardiac energetics in the resting subject are substantially stable until the onset of heart failure, when PCr falls significantly. In patients with coronary artery disease, metabolic levels can be modulated by exercise. As an alternative to exercise, the positive inotrope atropine-dobutamine has been administered to normal subjects, and at high cardiac output a reduction in the PCr:ATP ratio has been observed.

Intracellular pH is difficult to measure because the P_i peaks can be obscured by 2, 3-DPG in the blood. However, it is possible to overcome this problem using proton decoupling to sharpen the resonances, or saturation transfer to identify the intracellular P_i unambiguously.

Applications in Brain

Using animal models, many disorders of the brain have been studied, including the effects of ischaemia (e.g. models of stroke and birth asphyxia), systemic disturbances (e.g. hepatic encephalopathy) and genetic abnormalities (e.g. models of Duchenne dystrophy). Spatial localization is usually kept to a minimum – often the scalp is removed to avoid contamination by signals from the cranial musculature, and a single surface coil is used to obtain the ^{31}P NMR signal either from the whole brain or, by appropriate placing of the coil, predominantly from

Figure 3 A schematic diagram of energy metabolism in skeletal muscle, heart and brain. The creatine kinase pathway is absent in liver.

a single hemisphere. Almost invariably it is the energy metabolism of the brain which is of interest.

There have been many studies using ³¹P NMR to assess disease processes in man. Perhaps the most interesting have been the investigation of birth asphyxia in neonates where energy metabolite levels and intracellular pH give direct measures of brain damage and provide a good prognostic index. Other disorders which have been investigated include stroke, multiple sclerosis, epilepsy, hydrocephalus, tumours, dementias and systemic encephalopathies. In all cases there have been reports of altered energy metabolism (reduced PCr or increased P_i) and, in multiple sclerosis, changes have been observed in the broad phospholipid peak. The pH data are somewhat more variable – acidic values have been reported in acute stroke and hydrocephalus, but alkaline values have been observed in chronic stroke and brain tumours. One of the main limitations in performing ³¹P NMR spectroscopy in the human brain is that the spatial resolution is inadequate for interrogating focal lesions of moderate size. Nevertheless the global pictures that have emerged give insight into the way that brain energetics respond in disease.

Applications in Liver

The liver is relatively simple to study *in vivo* by ³¹P spectroscopy. On a macroscopic level it is homogeneous, and localization is generally straightforward. Since hepatocytes do not express creatine kinase, the liver contains no detectable phosphocreatine and so the degree of contamination of the liver spectra by signals from overlying muscle can be readily assessed (and in some cases corrected for).

Localization strategies have ranged from simple surface coil detection (with a hard 180° inversion pulse at the surface to suppress the muscle signal) through Fourier series window approaches and ISIS to one-, two- or three-dimensional chemical shift imaging. Proton decoupling and NOE irradiation have occasionally been employed, but the technical requirements and power deposition considerations have limited these to a few cases. In animal studies, localization methods are often avoided by exposing the liver and using a surface coil placed directly on the organ.

Liver Metabolism

The liver's role is to maintain chemical homeostasis and it can, in certain circumstances, be stressed by means of a metabolic load. One example has been to administer an oral fructose load which causes minimal spectral changes in normal subjects but, at very low dosage, results in an increase in the fructose-1-phosphate peak in patients with fructose intolerance. Other metabolic stresses have

been administered to investigate galactose intolerance, glycogen storage diseases and cirrhosis. The rat liver (*in situ* or perfused) has been studied to elucidate details of carbohydrate and fatty acid metabolism, sometimes by a combination of ¹³C and ³¹P NMR. The control of pH in the liver has also been studied.

Liver Diseases

Some common diseases that involve the liver have also been studied by ³¹P NMR. These include alcoholic liver disease, hepatitis, cirrhosis of various etiologies and liver tumours. The findings have often allowed the diseased liver to be distinguished from the healthy one, but the changes have not usually been specific to a particular disease and the interpretation of the changes is often speculative. Overall, these studies have shown that the major long-term changes in liver spectra involve the PME and the PDE signals, which probably signify changes in phospholipid metabolism (see below) while the energetics of the liver (assessed from the P_i:ATP ratio and the pH) remains normal until a very late stage of disease. Another area that shows promise is in assessing the transplanted liver, either before or after transplantation.

Spectral Interpretation

The PME and the PDE signals in the liver spectrum are each composed of several components, which cannot generally be resolved, except with the use of proton decoupling. Aqueous extracts show that the PME signal contains primarily phosphoethanolamine and phosphocholine, with contributions from 2, 3-DPG from blood and other minor components such as AMP, glucose-6-phosphate, *sn*-glycerol-1-phosphate and 3-phosphoglycerate. The PDE signal (at the low magnetic field strengths used for whole-body studies) is mostly composed of signals from phospholipid headgroups, broadened by chemical shift anisotropy and proton-phosphorus dipolar coupling, and also contains signals from GPE and GPC. These can be resolved by proton decoupling as can the PME signal, but this has rarely been undertaken.

Applications in Cancer

From the first ³¹P NMR studies of tumours *in vivo*, the differences between tumour spectra and those from other tissues were obvious. The tumour spectra were dominated by the PME signal, and the pH was found to be higher than in most other tissues. While these findings had potential use in distinguishing cancerous from normal tissue, it was hoped that subtle differences in the spectra would also help in determining the type or grade of the tumour, but these hopes have to a large extent not

been realized. Indeed some non-cancerous tissues, such as the regenerating liver or the neonatal brain, also show these characteristics.

The PME signal in most tumour types is predominantly composed of phosphoethanolamine, with variable contributions from phosphocholine. These molecules are precursors (and breakdown products) of membrane phospholipids, and it has been suggested that high levels may indicate a rapid rate of membrane turnover, although this has not been shown experimentally. Where proton decoupling has been applied, the relative amounts of phosphoethanolamine, phosphocholine, GPE and GPC can be assessed separately, and this may lead to a better biochemical explanation of the changes.

pH of Tumour Cells

Because tumour cells tend to be glycolytic, their pH was expected to be low. It was therefore a surprise to find that the NMR-determined pH was high (about 7.4, similar to that in blood plasma). These findings have been explained by the intracellular pH being kept high by the extrusion of protons into the extracellular space, which has a low pH, as shown by microelectrode studies. This 'reverse pH gradient' (opposite to that found in most cells) has implications for the uptake of drugs, and drug design.

Response to Therapy

Various groups have studied the response of tumours to therapy, both in patients and in experimental models. The results of such studies are often affected by partial volume effects, i.e. apparent metabolic changes in the tumour may simply be the result of the tumour shrinking, and the spectra containing more signal from the surrounding tissue. The most consistent findings are that tumours that respond to chemotherapy show a greater decrease in the PME:ATP ratio than do non-responders (**Figure 4**). In some cases, these changes take place before any measurable change in tumour size. Changes in pH and Pi:ATP ratios have also been reported. Experimental manipulation of tumour pH and blood flow, together with radiotherapy or chemotherapy, in implanted tumours in

Figure 4 An example of response to chemotherapy in the lymphomatous liver. Note the dramatic change in the PME peak: (a) before chemotherapy, (b) following chemotherapy.

animals have led to a greater understanding of the way in which tumours respond to therapy.

Introduction

Collisions between an ion and neutral species result in a number of possible outcomes depending upon the chemical and physical properties of the two reactants, their relative velocities, and the impact parameter of their trajectories. These include elastic and inelastic scattering of the colliding particles, charge transfer (including dissociative charge transfer), atom abstraction, complex formation and dissociation of the colliding ion. Each of these reactions may be characterized in terms of their energy-dependent rate coefficients, cross sections and reaction kinetics. This article outlines a theoretical framework for discussing these processes that emphasizes simple models and classical mechanics. We divide the discussion of collision processes into the two categories of low-energy and high-energy collisions. Experiments under thermal or quasi-thermal conditions—swarms, drift tubes, chemical ionization and ion cyclotron resonance—are strongly influenced by long-range forces and often involve ‘capture collisions’ in which atom exchange and extensive energy exchange are common characteristics. High-energy collisions are typically impulsive, involve short-range intermolecular forces and are direct, fast processes.

Low-Energy Collisions

For historical reasons, and because the majority of investigations of ion–molecule reactions have involved quasi-thermal collisions of relatively low-mass ions and neutrals, we begin with the simplest case of a point charge

interacting with a polarizable neutral. It is recognized that this Langevin model applies only at low collision energies where long-range forces dominate collision dynamics. Despite these restrictions, this simplistic picture provides a near-quantitative rationalization for the rates of thousands of ion–molecule reactions.

Ion–molecule collisions at low energies are dominated by the attractive long-range polarization force described in the simplest case by

$$V(r) = -\frac{\alpha q^2}{2r^4} \quad [1]$$

where the ion is tacitly assumed to be a point charge, q , and the neutral is a point polarizable atom or molecule having a polarizability α at a distance r from the ion. At relative velocities where repulsive forces can be neglected (that is, they are sensed at much closer distances than the impact parameter for orbiting collisions, as discussed below), eqn [1] is a plausible approximation. Conservation of angular momentum in a collision is imposed by expressing the effective potential of the ion–molecule system as the sum of the central potential energy $V(r)$ and the centrifugal potential energy:

$$V_{\text{eff}}(r) = -\frac{q^2\alpha}{2r^4} + \frac{L^2}{2\mu r^2} \quad [2]$$

where L is the classical orbital angular momentum of the two particles and μ is the reduced mass of the system. Here L is given by μvb where b is the impact parameter and v is relative velocity. The total relative energy of the system is given by

$$E_r = E_{\text{trans}}(r) + V_{\text{eff}}(r) \quad [3]$$

where $E_{\text{trans}}(r)$ is the translational energy along the line of centres of the collision.

A plot of $V_{\text{eff}}(r)$ versus r at constant E_r for several values of the impact parameter is shown in **Figure 1** for the collisions of N_2^+ with N_2 . For the special case in which the centrifugal barrier height equals E_r (at $b = b_c$ in **Figure 1**), $E_{\text{trans}}(r) = 0$, and the particles will orbit the scattering centre with a constant separation distance r_c . For $b > b_c$ the distance of closest approach $\geq b_c/\sqrt{2}$ and for $b < b_c$ the particles spiral into small radii before they separate. The cross section for orbiting collisions is

$$\sigma(v) = \pi b_c^2(v) \quad [4]$$

The rate coefficient corresponding to the orbiting or capture cross section is given by

$$k_c = v\sigma_c = v\pi q(2\alpha/E_r)^{1/2} = 2\pi q(\alpha/\mu)^{1/2} \quad [5]$$

which is the commonly cited energy (velocity)-independent Langevin rate constant for ion–molecule reactions. Use of these expressions implicitly assumes there

Figure 1 Plot of effective potential, V_{eff} , versus r for N_2^+ colliding with N_2 at a fixed energy of E_r and several values of the impact parameter. Reproduced with permission of Academic Press from Su T and Bowers MT (1979) In: Bowers MT (ed.) *Gas Phase Ion Chemistry*, vol. 1.

is a reactive cross section σ_{rx} for real systems which is smaller than the capture cross section given by eqn [4].

The reaction cross section also sets a conceptual limit of relative velocity beyond which treatments of only long-range critical potentials cannot apply. For a hypothetical example of $\sigma_{\text{rx}} = 50 \text{ Å}^2$, polarizability of 10 Å^3 and reduced mass of 50 amu, the capture cross section equals the σ_{rx} at a centre-of-mass (CM) collision energy of approximately 0.7 eV. We may infer that collision energies of the order of 1 eV roughly define the boundary between low-energy collisions – e.g. reactions in high-pressure ion sources, drift tubes, ion cyclotron resonance and plasma swarm experiments – and higher-energy collisions, considered later. Considering these limitations, it is remarkable that this simplistic theory accurately correlates collision cross section and rate coefficients for hundreds of reactions of ions with nonpolar molecules.

Ion–Dipole and Ion–Quadrupole Interactions

Over time, increasingly sophisticated modifications to the Langevin capture cross-section model have been developed to rationalize cross sections larger than Langevin and the temperature/energy dependences of cross sections. Considering first ion–dipole interactions, the classical expression for the effective potential is

$$V(r, \theta) = \frac{L^2}{2\mu r^2} - \frac{\alpha q^2}{2r^4} - \frac{\mu_D q}{r^2} \cos \theta \quad [6]$$

where μ_D is the dipole moment of the molecule and θ is the angle between the dipole and the line of centres of the collision. The first such treatment by Hamill and co-workers assumed that the dipole ‘locks in’ on the ion, i.e. $\theta = 0$. This upper limit, locked-dipole approximation, is obviously unrealistic for reactions at and above room temperature, for which rotation of the polar molecule tends to average out the dipolar potential.

Addressing this limitation, Su and Bowers developed the average dipole orientation (ADO) theory in which the orientation angle of the dipole with respect to the line of centres of collision is averaged as a function of ion–molecule separation distance. This concept leads to a ‘locking constant’, c , which is multiplied by the $\cos \theta$ term; this constant has been parametrized as a function of $\mu_D/\alpha^{1/2}$ for the range of temperatures that are of general interest in low-energy ion–molecule reactions. Further elaboration of this approach by Su and Bowers modified the treatment of angular momentum to formalize angle-averaged dipole orientation (AADO) theory. These workers also considered the interaction with a point charge of the quadrupole moment of molecules with $D_{\infty h}$ symmetry and formulated the average quadrupole orientation (AQO) theory for these types of long-range interaction.

Barker and Ridge developed a statistical model for ion–polar molecule collisions based on similar concepts. They considered the average interaction energy for a statistical ensemble of ion–neutral pairs as a function of their separation. The effective potential for such an ensemble is

$$V(r) = -\frac{\alpha q^2}{2r^4} - \frac{\mu q}{r^2} \mathcal{L}\left[\frac{\mu q}{r^2 k_B T_R}\right] + \frac{Eb^2}{r^2} \quad [7]$$

where k_B is the Boltzmann constant, T_R is the rotational temperature of the neutral, E is the relative translational energy, b is the impact parameter and $\mathcal{L}(X)$ is the Langevin function defined as $\mathcal{L}(X) = \coth(X) - 1/X$. The momentum transfer collision frequencies calculated from this model or from the family of ADO theories described above are in reasonable agreement with experimental measurements of rate coefficients. They rationalize both the larger cross sections found for ion–molecule reactions involving highly polar neutrals and the increase in reaction rate coefficients for polar molecules at low temperatures.

Quantum-Mechanical Approaches

Quantum-mechanical calculations of ion–dipole capture rate constants have been modelled successfully for low-temperature experiments and correlate well with the classical collision theory and capture cross sections just described. Clary has calculated rate constants of several ion–molecule reactions using the adiabatic capture

centrifugal sudden approximation (ACCSA). Since the rotational motion of the neutral is strongly hindered by the ion at low velocity, he chose collinear reaction geometry, leading to a basis set that localizes the rotational motion of the neutral about this collinear configuration. The partial wave Hamiltonian for the entrance reaction channel is given by

$$H = -\frac{\hbar^2}{2\mu r} \frac{d^2}{dr^2} r + Bj^2 + \frac{|J-j|^2}{2\mu r^2} + V(r, \theta) \quad [8]$$

where $\hbar$ is Planck’s constant divided by 2π , μ is the reduced mass, B is the rotational constant, j is the rotational angular momentum operator, J is the total angular momentum operator, V is the ion–molecule potential energy surface, θ is the orientation angle and r is the position vector of the particle measured from the centre-of-mass. As an approximation, $|J-j|^2$ is replaced by the diagonal value $[J(J+1)\hbar^2 + j^2 - 2\hbar^2\Omega^2]$, where Ω is the projection of both rotational and total angular momentum along the Z axis (centre-of-mass vector). Thus for a fixed value of r , the Hamiltonian becomes

$$H = Bj^2 + \frac{1}{2\mu r^2}(j^2 - 2\Omega^2\hbar^2) + V(r, \theta) \quad [9]$$

The reaction cross section is obtained from partial wave expansion and the capture approximation discussed earlier; that is, the reaction takes place if there is enough energy to surmount the centrifugal barrier. It follows that

$$\sigma(j) = \frac{\pi}{k_j^2(2j+1)} \sum_{J=0}^{J_{\max}(j, \Omega)} \sum_{\Omega=-\min(J, j)}^{\min(J, j)} (2J+1) P_j^{J\Omega} \quad [10]$$

where $P_j^{J\Omega}$ is the reaction probability. When $J_{\max}(j, \Omega)$ is larger than j , the sum over J in this equation gives the relationship

$$\sigma(j) = \frac{\pi}{k_j^2(2j+1)} \left[\sum_{\Omega=-j}^j (J_{\max}(j, \Omega) + 1)^2 - (2j+1)(j+1)^{(j/3)} \right] \quad [11]$$

with the condition that $\sigma(j) = 0$ if the energy is below the centrifugal barrier. Rate constants calculated by this formalism are in excellent agreement with experimental room-temperature constants for such systems as positive and negative ion–molecule reactions of HCN with H^- , D^- and H_3^+ ions.

Troe has used a statistical adiabatic channel model to calculate thermal ion–molecule capture rates using a pure long-range potential. The adiabatic channel potentials $V(r)$ are calculated from perturbation theory, and analytical expressions for channel threshold energies, activated complex partition functions and capture rate constants are obtained. His results are in good agreement with trajectory

calculations at temperatures above 10 K for such systems as $\text{H}_3^+ + \text{HCN}$. Additionally, Sakimoto has developed a time-independent quantum-mechanical approach for collinear triatomic systems $\text{A} + \text{BC}$ in the energy range from thermal to several eV. Using hyperspherical coordinates, the time-independent Schrödinger equation is solved numerically using the discrete variable representation algorithm for collision energies of 1–6 eV. Partial cross sections for reactive scattering and ion dissociation for $\text{He} + \text{H}_2^+$ (plus isotopes) were calculated that generally agree with limited experimental data for this system.

High-Energy Ion–Neutral Collisions: Beam Scattering

Low-energy ion–neutral collisions considered thus far often result in random angular scattering with extensive mixing of orbital and angular momentum. Beam experiments at the low-energy limit demonstrate that persistent complexes are formed but provide no further information on reaction mechanisms. In contrast, conservation of angular momentum in high-energy collisions leads to specific angular scattering, which can provide detailed information on reaction mechanisms. Deducing this information is a complex exercise and we begin with a description of elastic scattering. After these scattering characteristics have been described – both classically and quantum mechanically – we shall outline briefly how reactive scattering is treated in this framework. A collision is better described by CM coordinates, which permit us to describe kinetic energy T as the motion of the centre-of-mass of the system in the laboratory frame and the relative motion of the particles in the CM frame

$$T = \frac{1}{2} M V_{\text{CM}}^2 + \frac{1}{2} \mu v^2 \quad [12]$$

where M is the sum of the masses, V_{CM} is the velocity of the CM and the reduced mass and relative velocity have been defined previously. Since the motion of the CM is conserved in any collision, we can focus our attention on the relative motion in which the two particles are described as a single particle having mass μ , angular momentum $\mu(r \times v)$ and kinetic energy $\frac{1}{2} \mu v^2$.

For central potentials considered previously, the angular momentum is constant and the total CM energy at separation r is

$$E = \frac{1}{2} \mu \left[\frac{dr}{dt} \right]^2 + V_{\text{eff}}(r) \quad [13]$$

where the effective potential

$$V_{\text{eff}}(r) = V(r) + \frac{L^2}{2\mu r^2} \quad [14]$$

includes the centrifugal potential $L^2/2\mu r^2$ described previously. The centrifugal potential is included in the equation for radial motion to account for angular motion of the system.

The observable results of a collision are the velocity of the particle after collision (deduced from its kinetic energy) and its direction of motion. For ordinary collisions between spherical particles, total kinetic energy must be conserved, so the initial and final velocities must be equal at distances large enough that $V(r)$ is negligible. **Figure 2** depicts how the deflection angle – the quantity of interest in these elastic and nonreactive collisions – relates to the interaction potential. Here a particle of reduced mass μ approaches parallel to the x axis with kinetic energy $\frac{1}{2} \mu v^2$ and angular momentum $\mu v b$. When the effective potential energy V_{eff} equals the initial kinetic energy, the particle reaches its distance of closest approach, r_c , the turning point of the trajectory. The particle then recedes, and at a large distance from the scattering centre no longer senses the interaction potential. The change in direction of motion is the deflection angle θ , and is measured from the negative x axis in **Figure 2**. We note parenthetically that deflection through $+\theta$ and $-\theta$ are experimentally indistinguishable and that deflection by $\pm 2\pi N\theta$ (where N is an integer) is indistinguishable from the deflection θ .

Figure 2 illustrates that the deflection is symmetric about the turning point; that is, the deflection of the particle in the outgoing trajectory equals its deflection in the approach trajectory for elastic scattering. Consequently, the polar scattering angle is $2\phi_c$ and the final scattering angle θ is $\pi - 2\phi_c$ (see **Figure 2**). This leads to the expression for the deflection angle as a function of initial energy and impact parameter:

$$\phi(b, E) = \pi - 2b \int_{r_c}^{\infty} \frac{dr}{r^2} \left[1 - \frac{V(r)}{E} - \frac{b^2}{r^2} \right]^{1/2} \quad [15]$$

Figure 2 Deflection of particles interacting through a potential $V(r)$. A single particle of reduced mass μ and velocity v moves towards the stationary scattering centre with impact parameter b and is scattered by a central potential $V(r)$ through an angle θ . where r_c is the outermost solution of $E = L^2/2\mu r_c^2 + V(r_c)$. Note that if $b = 0$ (head-on collision), then $\theta = \pi$ (unless $V = 0$). Further, as b increases from zero, θ decreases from π , and θ decreases to zero as b increases without limit.

A reasonable central force potential for ion–neutral elastic scattering is the Morse potential given by

$$V(r) = D(e^{-2x} - 2e^{-x}) \quad [16]$$

where $x = \alpha(r - r_e)$, with α specifying the curvature of the potential at its minimum. This potential has an attractive well of depth D at the equilibrium separation, $r = r_e$. For $r < r_e$, the repulsive part of the potential rises steeply to a high value, for $r > r_e$ the attractive part of the potential is dominant. Because the Morse potential goes to zero exponentially, it does not correctly describe the potential at large r . If necessary, it can be modified by adding a term for long-range polarization forces. It nicely describes the short-range behaviour and the balance between attractive and repulsive forces.

Differential Scattering

To illustrate the relationship between potential and scattering, **Figures 3–5** show respectively the effective potential, deflection function and scattering intensity for the Morse potential, (eqn [16]), parameterized to describe scattering of low-energy protons by argon atoms. The potential for zero impact parameter (hence zero angular momentum, $L = 0$) in **Figure 3** has the parameters $r_e = 1.28 \text{ \AA}$, $D = 4.17 \text{ eV}$ and $\alpha = 1.85 \text{ \AA}^{-1}$; the

Figure 3 Plot of effective potentials derived using the Morse potential for several values of angular momentum, L , as marked on each curve. See text for the parameters used for the Morse potential. Reproduced with permission of John Wiley from Shirts RB (1986) In: Futrell JH (ed.) *Gaseous Ion Chemistry and Mass Spectrometry*.

Morse potential with these parameters matches the experimentally determined scattering of protons by argon to better than 1% accuracy over the interval from 0 to 5 Å.

The curves in **Figure 3** are labelled with the angular momentum, L , in units of $\hbar$. At high L , the centrifugal potential overpowers the attractive well and the scattering is always repulsive. At $L = 75.95\hbar$ there is an inflection point at $V = 1.153 \text{ eV}$, and for lower angular momenta collisions the effective potential has two regions of repulsion separated by an attractive well. The outermost root is the classical turning point for the potential and a plot of the turning point r as a function of impact parameter (or, equivalently, of L) leads to a singularity where $\sqrt{e} = b$ for all collision energies. This corresponds to the point where the potential $V(r) = 0$ [$\sim 1 \text{ \AA}$ for the potential shown in **Figure 3**] and is a measure of the ‘size’ of the interacting particles, analogous to but different from a hard-sphere radius for the collision.

Figure 4 shows the deflection function calculated from eqn [15] for the effective potential given in **Figure 3** for a number of collision energies. For zero impact parameter, the deflection angle is π , just as it would be for hard-sphere collisions, with positive scattering angle corresponding to repulsive collisions. The deflection angle goes through zero and becomes negative as the collision senses the attractive potential at longer distances. As b increases, the deflection angle goes

smoothly to zero. For moderate energy collisions, the centrifugal potential dominates scattering at all impact parameters. For very low energies, <1.153 eV for the potential illustrated, there are three roots of the deflection function. (The reader is reminded that positive and negative deflections are experimentally equivalent.) The ‘piling up’ of intensity at a particular scattering angle is called the rainbow angle. Measurement of rainbow scattering is an important experimental parameter for deducing the scattering potential. For specific L values below this critical energy, two of the roots coincide at the maximum of the effective potential. For these trajectories, orbiting occurs and the deflection angle becomes infinite. This phenomenon is readily detected in careful beam scattering experiments; it corresponds to the capture cross section in our description of low-energy collisions.

Figure 5 illustrates the connection of crossed-beam measurements of ion scattering with the interaction potential of the ion–neutral collision, again using the Morse potential. The quantity measured experimentally is the differential scattering cross section for a given CM collision energy. The differential cross section, $I(\theta)$, at a specified energy is given by

$$I(\theta)d\Omega = \frac{I(b)}{I_0} = I(\theta)[2\pi \sin\theta \, d\theta] = 2\pi b \, db \quad [17]$$

$$I(\theta) = \frac{b}{[\sin\theta(d\theta/db)]} \quad [18]$$

where $d\Omega$ is the differential of the solid angle. The cross section calculated for the Morse potential shown in

Figure 5 illustrates for several energies the singularities determined by the two terms in the denominator of eqn [18]. The $\sin\theta$ term gives an infinity at CM angles of zero and π . The rainbow angle gives rise to a singularity when $d\theta/db$ goes to zero; this occurs when several impact parameters give the same deflection angle. At higher collision energies this occurs at small angles; with decreasing collision energy the rainbow angle increases smoothly with decreasing energy and, for 1.5 eV, is greater than 180° . Numerically it is 254° for this potential, leading to an observed scattering angle of $360^\circ - 254^\circ = 106^\circ$. Two details distinguish this class of trajectories experiment from high energy collisions – namely, the singularity at 180° and the reversal of the ‘bright side’ of the rainbow. The backscattering of particles corresponding to the $\sin\theta$ singularity at 180° is the experimental demonstration that particles are scattered by a potential sufficiently attractive at that collision energy to hold them together for at least half a revolution.

Reactive Encounters

We have explained in some detail the relationship of measured variables in elastic scattering to the interaction potential between the ion and the neutral. This framework is the starting point for describing inelastic and reactive scattering. Inelastic scattering may be introduced as an instantaneous conversion of kinetic energy of motion into internal energy of either or both of the collision partners, while reactive collisions involve both energy exchange and reaction. It is plausible that these physical and chemical conversions occur at or near the distance of closest approach in the respective trajectories. This breaks the symmetry of the elastic scattering formalism and the retreat trajectory of products involves both a different energy inventory in the collision partners and a change in the potential governing the trajectory as they separate from the collision centre. This approach has been reasonably successful in rationalizing the differential scattering cross sections of a variety of proton transfer reactions. The time-dependent quantum-mechanical treatment of collisions described in the next section automatically takes into account energy transfer and reaction – at least in principle.

Newton Diagrams

As noted previously, describing collision processes in the CM frame is more informative than in the laboratory (LAB) frame. Explicitly the motion of the CM is conserved in collisions and is unavailable to the reactants. The proper framework for displaying collisions is the CM relative velocity diagram, frequently called the

Figure 6 Newton diagram showing pre- and postcollision velocity vectors in the laboratory and centre-of-mass reference frames for the collision of M_1^+ and M_2 having velocities of V_1 and V_2 .

Newton diagram. The collision process (for simplicity assumed to occur at right angles) of

with M_1^+ and M_2 , having velocities of V_1 and V_2 , is depicted in **Figure 6**. The collision centre is the origin of the laboratory reference frame. In the CM frame, M_1^+ and M_2 move collinearly towards each other with velocities U_1 and U_2 and collide at the CM located on their relative velocity vector at the point defined by conservation of momentum such that $M_1 U_1 = M_2 U_2$. After collision, the two particles recoil from the CM in opposite direction with velocities U_1' and U_2' . The velocity of the CM is given by

$$V_{CM} = \frac{M_1 V_1}{M_1 + M_2} + \frac{M_2 V_2}{M_1 + M_2} \quad [20]$$

and is constant. The relative kinetic energy of the collision partners, E_{CM} , is available for the reaction and is given by

$$E_{CM} = \frac{1}{2} M_1 U_1^2 \left(1 + \frac{M_1}{M_2} \right) \quad [21]$$

Similarly, the postcollision relative kinetic energy is given by

$$E'_{CM} = \frac{1}{2} M_1 U_1'^2 \left(1 + \frac{M_1}{M_2} \right) \quad [22]$$

The difference $\Delta T = E'_{CM} - E_{CM}$, the translational exoergicity of the collision process, is a direct measure of the energy used in the process. Consequently, experimental measurements and transformation of mass, intensity, energy and angular distributions of product ions as Newton diagrams provide quantitative information on the energetics and dynamics of the collision process.

Two limiting cases of ion–molecule reaction dynamics will serve to illustrate the utility of Newton diagrams. If a

collision between an ion and a molecule proceeds via an intermediate whose lifetime is longer than several rotational periods ($\sim 10^{-12}$ s), internal energy redistribution is usually complete and the complex loses its memory of the reactant velocity vectors. The products will separate with equal probability on both sides of a plane passing through the CM and normal to the collision axis, giving rise to the forward–backward symmetry. Such orbiting complexes are usually formed at relative kinetic energies that are of the order of or less than the well depth of the interaction potential governing the collision.

As relative kinetic energy increases, the lifetime of the intermediate complex decreases and there is a transition to a direct reaction. The interaction time is too short for the intermediate to rotate and the Newton diagram contour plot becomes asymmetric with respect to the CM. The dependence of reaction probability on impact parameter and the effective potential for the approach and retreat trajectories determine the scattering angle and the form of the Newton diagram.

Semiclassical Theory of Collisions, the WKB Phase Shift

In three dimensions and for central potentials, the Schrödinger equation separates in spherical coordinates analogously to corresponding classical equations of motion. The incoming particle is described by a wavefunction with a local wavenumber $k(r)$. Repulsive potentials decrease the velocity of the wave packet and the resulting scattered wavefunction has fewer nodes, resulting in a negative phase shift. Conversely, attractive potentials result in an increase in velocity; the wavefunction acquires more nodes and this results in a positive phase shift. The overall phase shift for scattered particles is

$$\delta(E, b) = \int_{\text{actual path}} k(r) \, dr - \int_{\text{unscattered path}} k_0(r) \, dr \quad [23]$$

Integrating this expression from the distance of closest approach to infinity (this gives half the total difference in phase for the entire trajectory; this is the convention for phase shift) gives

$$\delta(E, b) = \frac{\mu v}{b} \lim_{R \rightarrow \infty} \left[\int_{r_c}^R \left(1 - \frac{V(r)}{E} - \frac{b^2}{r^2} \right)^{1/2} dr - \int_b^R \left(1 - \frac{b^2}{r^2} \right)^{1/2} dr \right] \quad [24]$$

For both integrals, the lower limit of integration is the (outermost) zero of the associated integrand. Since both integrals are divergent, δ depends on cancellation between the two. This difficulty is repaired by subtracting $\int_{r_c}^R dr$ from both terms:

$$\delta(E, b) = \frac{\mu v}{\hbar} \left[\int_{r_c}^{\infty} \left(1 - \frac{v(r)}{E} - \frac{b^2}{r^2} \right)^{1/2} - 1 \right] dr - r_c + \frac{\pi b}{2} \quad [25]$$

This may be recast into a form incorporating the definition of phase shift from eqn [23]:

$$\delta(E, b) = \int_{r_c}^{\infty} (k(r) - k) dr - k \left(r_c - \frac{\pi b}{2} \right) \quad [26]$$

where the integral term gives the phase difference resulting from the interaction potential and a correction for the difference in turning points of the unscattered and scattered particle includes the effect of the centrifugal potential.

Finally, it can be shown that the phase shift method leads to expressions for the collision time (different between $V(n) \neq 0$ and $V(n) = 0$) and for scattering angle.

$$\tau(E, b) = 2\hbar \left(\frac{\partial \delta(E, b)}{\partial E} \right)_b \quad [27]$$

$$\theta(E, b) = \frac{2\hbar}{\mu v} \left(\frac{\partial \delta(E, b)}{\partial E} \right)_E \quad [28]$$

This makes the precise connection we seek between WKB scattering theory and the classical model developed previously.

Quantum Scattering

Moving from a semiclassical towards a full quantum treatment we note that, at large distances, the wavefunction for a scattered particle is a combination of an incoming plane wave and a scattered wave:

$$\psi(r, \theta) = e^{ikz} + \frac{f(\theta)}{r} e^{ikr} \quad [29]$$

where the z direction is the direction of travel. The first term describes a plane wave and the second term is an outgoing spherical wave whose amplitude is $f(\theta)$. This simple form of the wavefunction is valid for r large enough that no interference between the incoming and outgoing waves is important. This applies experimentally to a collimated beam of finite width.

Since the wavefunction in eqn [29] obeys the Schrödinger equation, it can be expanded in any complete set of orthogonal functions, for example Legendre polynomials:

$$\psi(r, \theta) = \sum_{l=0}^{\infty} \frac{\psi_l(r)}{kr} P_l(\cos \theta) (2l+1) i^l \quad [30]$$

where P_l is Legendre polynomial. Multiplying by $P_l(\cos \theta)$, and integrating over θ we obtain for large values of r the asymptotic result

$$\left(\frac{d^2}{dr^2} + k^2 \right) \psi_l(r) = 0 \quad [31]$$

which has solutions $\psi_l(r) = a_l \sin(kr - l\pi/2 + \delta_l)$. Here the phase shift, δ_l , for the l th partial wave contains all the information about the potential, and the term $l\pi/2$ comprises the centrifugal potential. The expression for scattering amplitude is obtained as

$$f(\theta) = \sum_{l=0}^{\infty} \frac{2l+1}{k} e^{i\delta_l} \sin \delta_l P_l(\cos \theta) \quad [32]$$

The differential cross section $I(\theta)$ is the probability density for observing a particle at an angle θ , $|f(\theta)|^2$ and the total cross section is obtained by integration of $I(\theta)$ over all angles as given below.

$$\sigma = \frac{4\pi}{k^2} \sum_{l=0}^{\infty} (2l+1) \sin^2 \delta_l \quad [33]$$

Figure 7 Plot of scattering intensity versus centre-of-mass scattering angle at 5 eV collision energy using quantum-mechanical treatment. The calculations were performed using 500 phase shifts and the Morse potential of **Figure 3**. Reproduced with permission of John Wiley from Shirts RB (1986) In: Futrell JH (ed.) *Gaseous Ion Chemistry and Mass Spectrometry*.

The phase shifts for calculating scattering as a function of angle are obtained by starting at $r=0$ and increasing r until $V(r)$ becomes negligible.

Figure 7 illustrates the differential cross section for the Morse potential (eqn [17]) calculated using eqn [32] and 500 phase shifts that were calculated using eqn [26]. The relative energy is 5 eV. The classical differential cross section from **Figure 5** is also shown. The quantum-mechanical form of $I(\theta)$ removes the classical singularity. The additional peaks occurring at angles smaller than the rainbow angle are interferences from the three different values of the impact parameter that contribute to scattering into these angles. The quantum result tends to oscillate about the classical mechanical result, which cannot recover the interferences of the quantum result.

For noncentral potentials – e.g. molecular scattering – the Schrödinger equation does not separate into partial waves. The solution can still be expanded in partial waves, but then the individual partial-wave radial Schrödinger equations will have additional terms that couple them together. Sophisticated computer programs are now available to solve these complex equations and calculate the detailed dynamics of a collision process.

Symbols

E	total energy
h	Plancks constant
k_B	Boltzmann constant
$k(E)$	unimolecular microcanonical rate constant
$k(T)$	canonical rate constant
N_0	initial number of ions formed
$N^\ddagger(E - E_0)$	number of states of the transition state up to $E - E_0$ above the critical energy E_0
$P(E)$	distribution of internal energies
$R(E, t)$	rate of dissociation
T	temperature
$\Delta H^\ddagger$	activation enthalpy
$\Delta S^\ddagger$	activation entropy
$\Delta S_\mu^\ddagger$	microcanonical entropy of activation
ν_R	reaction coordinate frequency
$\rho(E)$	density of states of the parent ion at internal energy E
σ	degeneracy of reaction path

The ionization process taking place in the source of a mass spectrometer or the activation step of a tandem mass spectrometry experiment leads to ions with a range of internal energies extending usually well above the first dissociation threshold, that is the molecular ion has enough energy to dissociate. Dissociation is a dynamic process characterized by its associated lifetime. The whole story of kinetics in general and of ion dissociation kinetics in particular is to measure how fast a dissociation proceeds under given conditions (state selection, well-defined energy or temperature, for example) and to determine the reaction mechanisms. Both aspects will be addressed.

Unimolecular Rate Constant

Dissociation kinetics of state-selected reactant ions has been investigated only in a limited number of relatively small systems. However, a large amount of data is now available on ionic reactions investigated with internal energy selection.

The dissociation of an energy-selected molecular ion is a unimolecular process, the rate of which, $R(E, t)$, is

defined by the following equation, where N_0 is the initial number of ions formed:

$$R(E, t) = \frac{dN_{AB^+}}{dt} = k_{AB^+}(E)N_{ABC^+}(E, t) \\ = k_{AB^+}(E)N_0 \exp(-k_{AB^+}(E)t)$$

This represents the most simple situation where a single dissociation process occurs for ions possessing a single total energy, E . $k(E)$ is called the unimolecular rate constant. However, in practice, the parent ion can be formed with a broad distribution of internal energies, $P(E)$, and competitive reactions can take place. If the different competitive channels are characterized by rate constants denoted $k_j(E)$, then the following equation holds for the rate of production of the j th fragment ion:

$$R_j(E, t) = \frac{dN_j}{dt} = N_0 \int_E dE k_j(E)P(E) \exp\left[-\sum_i k_i(E)t\right]$$

If further dissociations occur, the rates must be calculated by solving the set of differential equations resulting from the appropriate kinetic scheme.

If the dissociating ion is characterized by a well-defined internal energy, that is if $P(E)$ reduces to a single value, then each ion of the ionized sample can be considered to be one of the replicas of a microcanonical ensemble. For this reason, $k(E)$ is often referred to as the ‘microcanonical rate constant’. If, however, $P(E)$ is a thermal Boltzmann distribution characterized by a temperature T , then the corresponding rate constant, $k(T)$, is called the ‘canonical rate constant’.

One of the most widespread approaches to model the experimental microcanonical rate constant is the RRKM-QET (Rice–Ramsperger–Kessel–Marcus Quasi-equilibrium theory) statistical theory, which postulates that a rapid internal energy randomization takes place before dissociation and that a transition state can be defined. This leads to the following well-known equation:

$$k(E) = \frac{\sigma N^\ddagger(E - E_0)}{b\rho(E)}$$

where σ is the degeneracy of the reaction path (e.g. $\sigma = 4$ for the loss of H from CH_4), $N^\ddagger(E - E_0)$ is the number of states of the transition state up to an energy $E - E_0$ above the

critical energy E_0 and $\rho(E)$ is the density of states of the parent ion at the internal energy E .

If $k(E)$ is averaged over a thermal internal energy distribution at temperature T , the equation of transition state theory for the canonical rate constant is recovered. It can be expressed as a function of the activation entropy, $\Delta S^\ddagger$, and of the activation enthalpy, $\Delta H^\ddagger$.

$$k(T) = \frac{k_B T}{h} \exp\left[\frac{\Delta S^\ddagger}{R}\right] \exp\left[-\frac{\Delta H^\ddagger}{RT}\right]$$

where k_B and h are respectively Boltzmann's and Planck's constants. The value of the activation entropy gives insight into the looseness or the tightness of the transition state. Loose transition states are usually associated with simple bond cleavages, whereas rearrangement processes are expected to involve tighter transition states. Competitive processes, multistep fragmentations, nonadiabatic processes and tunnelling effects affect the variation of the rate constant with internal energy, which then forms a diagnostic tool to investigate such effects. Furthermore, as in neutral physical organic chemistry, kinetic isotope effects (mostly upon deuteration) are one of the most powerful tools to investigate the mechanisms of a chemical reaction.

Experimental Determination of the Microcanonical Rate Constant

Various experimental techniques are now available to measure the unimolecular rate constant over quite an extended range, typically from 10^2 to 10^{10} s^{-1} . Broadly speaking, most experiments can be classified in one or the other of the three following groups, depending on the rate constant range accessible: microsecond time window ($10^5 < k < 10^7 \text{ s}^{-1}$), nanosecond time window ($10^7 < k < 10^{10} \text{ s}^{-1}$) and millisecond time range ($10^2 < k < 10^5 \text{ s}^{-1}$). Trapping techniques are instrumental in this last range. The techniques pertaining to the first two groups are based on the fact that the kinetic energy acquired by a fragment ion produced within an accelerating electric field depends on the position (or, equivalently, on the time) at which dissociation took place. The rate constant can then be extracted from the shape of an ion kinetic energy spectrum or of a time-of-flight distribution. The rate constant range accessible in a given experiment depends on the magnitude of the electric field.

MicroSecond Time Window

Ions dissociating in the microsecond time window, that is with a rate constant in the $10^5 - 10^7 \text{ s}^{-1}$ range, have received considerable attention. This range is very often referred to as the metastable time frame and processes occurring within this time window are called metastable.

Photoelectron-photoion coincidence (PEPICO) spectroscopy is the technique of choice in this range. The most useful version of this technique, called threshold PEPICO (TPEPICO), initiated by Stockbauer and by Baer, uses a variable-wavelength photon source, nowadays in most cases a synchrotron or a tunable laser, and detects ions in delayed coincidence with zero-kinetic-energy electrons (threshold electrons). Under such conditions, the ion internal energy is equal to the photon energy less the adiabatic ionization energy of the molecule. By combining angular and time-of-flight discriminations of energetic electrons, a resolution of about 10 meV can be obtained. Even better resolutions are reached by using recent zero-kinetic-energy techniques. The data have to be corrected for the analyser apparatus function, for the thermal distribution of the parent ions and for the possible release of translational energy to the dissociation fragments. Extracting rate constant information in the presence of an appreciable translational energy release is somewhat hazardous.

The upper limit in the rate constant range accessible by threshold PEPICO is dictated by the extraction field which cannot exceed a few V cm^{-1} to maintain a reasonable energy resolution.

Another way of selecting ions with a well-defined internal energy involves multiphoton ionization (MPI) where the vibrationless ground state of the molecular ion is first prepared and then photo-dissociated by absorption of an additional photon. In practice, the upper rate constant limit is about the same as in PEPICO. The major advantage of MPI is that it makes rotational state selection possible, so that the influence of angular momentum on ionic fragmentations can be investigated.

Nanosecond Time Window

In field ionization, much higher electric fields can be achieved (of the order of 10^5 V cm^{-1}): the ions are then much more strongly accelerated, and dissociation decays in the nanosecond to picosecond range can be monitored. No internal energy selection is performed in such experiments. Nontrivial data handling procedures assuming some reasonable form for the internal energy distribution have been developed to obtain $k(E)$ data.

Photodissociation mass-analysed ion kinetic energy spectrometry (PD-MIKE) has been designed by Kim and co-workers to monitor nanosecond range decays. Laser photodissociation of mass-selected ions is induced in the presence of a strong electric field within the region located between the magnet and the electrostatic analyser of a reverse-geometry sector mass spectrometer (a region which would be otherwise field-free). The internal energy range of the parent ion prior to photodissociation is relatively broad but can be narrowed by collisional cooling inside the ion source.

Millisecond Time Window

Slow dissociation rates ($10^2 - 10^4 \text{ s}^{-1}$) have been measured in Dunbar's laboratory by time-resolved photodissociation, which consists of trapping ions in an ICR cell during a variable delay time after a photodissociating photon pulse. The technique called 'time-resolved photoionization mass spectrometry', developed by Lifshitz, consists of trapping photoions in a cylindrical trap at very low pressure to avoid bimolecular collisions, and then ejecting them into a mass filter after a variable delay covering the microsecond to millisecond range. When the dissociation rate constant becomes lower than *ca.* 10^3 s^{-1} , competition with infrared fluorescence takes place and limits the lifetime of the decomposition process. This has to be taken into account to extract the dissociation rate constant from the experimental data.

The rate constant for the $\text{C}_6\text{H}_5\text{Br}^{+\bullet} \rightarrow \text{C}_6\text{H}_5 + \text{Br}^\bullet$ reaction has been measured by all these experimental techniques, so that a broad range could be sampled (Figure 1). Note that very good agreement is obtained between independent measurements in the metastable domain.

Canonical Rate Constant

Flow tube techniques (flowing afterglow, selected ion flow tube) have been used extensively to study ion–molecule reactions and to measure their rate coefficients. There are far fewer studies on the thermal decomposition of gaseous ions. Recently, cluster ions and noncovalent complexes have, however, received considerable attention.

Dissociation rate constants of ions at atmospheric pressure have been obtained by ion mobility spectrometry. The time frame of such experiments is in the millisecond range. Dissociation rates of proton-bound amine dimer ions, for example, have been measured recently.

In the technique called 'blackbody infrared radiation dissociation' (BIRD), developed in E.R. Williams' laboratory, ions trapped in an ICR cell at very low pressure absorb infrared photons emitted by the cell walls. Dissociation decays in the second to minute time frame can be followed. In both techniques, the analysis of the temperature dependence of the rate constant leads to activation parameters. BIRD has been applied to biologically important noncovalent complexes like proton-bound dimers of amino acids or double-stranded DNA complexes.

Kinetic Isotope Effects

Isotope effects, mostly involving hydrogen–deuterium, are one of the most powerful tools for chemical kinetics investigations. The kinetic isotope effect is defined as the ratio of the rate constants corresponding to the unlabelled

Figure 1 Microcanonical rate constant for the $\text{C}_6\text{H}_5\text{Br}^{+\bullet} \rightarrow \text{C}_6\text{H}_5^+ + \text{Br}^\bullet$ decomposition obtained using various experimental techniques. (+) Baer *et al* (1976) (+) Baer *et al* (1982) (□) Rosenstock *et al* (1980) (Δ) Pratt and Chupka (1981) (■) Brand *et al* (1984) (●) Lim *et al* (1998) (○) Malinovich *et al* (1985).

and labelled species at a given internal energy. A distinction is made between intermolecular and intramolecular kinetic isotope effects. An intramolecular isotope effect refers to the competition, from a unique partially labelled molecular ion, between two channels differing only by the location of the heavier isotope, for example:

An intermolecular isotope effect refers to two equivalent dissociation pathways from two differently labelled molecules. As an example:

For intramolecular isotope effects, as one starts from a unique precursor, the two processes correspond to the same internal energy distribution, so that useful information can be inferred even from ion abundances measured without internal energy selection (like metastable dissociations or field ionization kinetics). This is not the case for intermolecular effects, where there is no warranty that the two internal energy distributions are the same. Within the RRKM framework, the intramolecular kinetic isotope effect depends only on the transition state properties (critical energy, rotational constants and vibrational frequencies) and not on the reactant properties.

In primary isotope effects, the isotopically substituted atom is directly involved in bond breaking or bond formation. In secondary isotope effects, the substituted atom is remote from the participating bond. Primary isotope effects occur largely because of changes in the critical energy E_0 upon labelling. Secondary isotope effects result from changes in the densities of states. Intermolecular secondary isotope effects can be larger than primary effects. The larger the critical energy, the larger the secondary isotope effect. A kinetic isotope effect, where k_H/k_D is larger than unity, is said to be normal. If $k_H/k_D < 1$, the effect is called inverse.

Isotope effects increase when internal energy decreases. Large effects are therefore expected in the metastable time range which corresponds to relatively low internal energies. Isotope effects are instrumental in (i) localizing the particular atoms involved in H-shift reactions, (ii) providing evidence of hydrogen scrambling, (iii) distinguishing between stepwise or concerted processes, (iv) postulating a reasonable structure for the transition state, and (v) deciding whether tunnelling is involved or not. Examples will be given in the next sections.

Reaction Mechanisms from Kinetic Data

We will consider, successively, reactions involving only one potential energy surface and those where at least two electronic states of the same or of a different multiplicity interact. These latter reactions are called nonadiabatic. Among the adiabatic reactions, we will move from the simple to the more complex, from one-step dissociations to competitive processes and finally to multistep fragmentations. While convenient, this classification is oversimplified. A multistep fragmentation, for example, can involve both adiabatic and nonadiabatic intermediate steps.

One-Step Dissociations

Dissociations of substituted benzene ions are probably among the most extensively studied ionic reactions. Most of them were satisfactorily modelled by the RRKM equation. The looseness or tightness of the transition

state is usually inferred from the value of the activation entropy (at a somewhat arbitrary temperature, usually 1000 K) resulting from the RRKM fit. A clear-cut positive value for $\Delta S_{1000\text{ K}}^\ddagger$ (usually not exceeding $35\text{ J K}^{-1}\text{ mol}^{-1}$) indicates a loose transition state, whereas a slightly positive or a negative value (usually not smaller than $-30\text{ J K}^{-1}\text{ mol}^{-1}$) is the signature of a tighter transition state. **Table 1** illustrates this for a few selected reactions, which are believed to involve a single dissociative step, that is to take place on a single-well potential energy surface.

At first sight, it might seem inconsistent to use a thermal quantity to characterize a microcanonical rate constant. However, the canonical rate constant is related, via a thermal average, to the microcanonical rate constant with the same transition state. The advantage of the canonical formulation is twofold. First, the essential information is compacted into two factors, the critical energy and the entropy of activation, rather than being scattered among many individual vibrational frequencies. Second, it makes a comparison possible with thermal data for the neutral counterpart of an ionic reaction. Alternatively, some authors calculate the microcanonical entropy of activation at infinite internal energy, so that the critical energy becomes negligible, according to:

$$\Delta S_\mu^\ddagger(E \rightarrow +\infty) = R \ln \frac{N^\ddagger(E - E_0 \rightarrow +\infty)}{h\nu_R \rho(E \rightarrow +\infty)}$$

Table 1 Entropies of activation for selected one-step dissociations

Reaction	$\Delta S_{1000\text{ K}}^\ddagger (\text{J K}^{-1}\text{ mol}^{-1})$

ν_R is the frequency associated with the reaction coordinate. For the $C_6H_6^{+\bullet} \rightarrow C_6H_5^+ + H^\bullet$ reaction, for example $\Delta S_{1000K}^\ddagger = 11.3 \text{ J K}^{-1} \text{ mol}^{-1}$ and $\Delta S_\mu^\ddagger(E \rightarrow +\infty) = 13.2 \text{ J K}^{-1} \text{ mol}^{-1}$. For the $C_2H_4^{+\bullet} \rightarrow C_2H_3^+ + H^\bullet$ reaction, the canonical and microcanonical entropies of activation amount to 32 and $36 \text{ J K}^{-1} \text{ mol}^{-1}$, respectively.

The large activation entropies observed for the dissociations of the bromo- and iodobenzene cations are compatible with a maximum entropy analysis of the product energy distributions, which leads to a nearly complete (about 80%) phase sampling. As illustrated in **Figure 1**, an excess energy of about 0.7 eV, called the 'kinetic shift' is necessary to bring the rate constant above 10^5 s^{-1} so that dissociation can be detected in the metastable window.

The dissociation of the styrene ion involves a transition state very similar to the reactant. The large negative entropy of activation results from the fact that the internal energy content of the transition state is reduced, compared to the reactant ion, by an amount equal to the critical energy. The transition state structure for the CO loss from the phenol cation is also close to the precursor but some vibrational modes loosen up, resulting in a slightly positive activation entropy.

Activation entropies result from a fitting procedure including the critical energy E_0 , too. In many cases, the limited range of internal energies investigated, as well as the lack of information on the structure and/or the thermochemistry of the fragments, and on a possible reverse activation barrier, preclude any reliable control over E_0 . One should therefore be aware of energy–entropy trade-offs.

Competitive Reactions

Ions generally have low isomerization barriers so that decomposition channels leading to different product ions with the same molecular formula can compete. Two examples will illustrate this point.

In contrast to the simple C–I bond cleavage observed with the iodobenzene cation, the corresponding reaction with the iodotoluene cation is much more complex, leading to a mixture of three $C_7H_7^+$ isomers with tolyl, benzyl and tropylium structures. The experimental data available have been analysed by Dunbar and co-workers using a two-channel model (**Figure 2**). The lowest energy channel leads to the benzyl and tropylium structures via a rearrangement characterized by a tight transition state ($\Delta S_{1000K}^\ddagger = -29 \text{ J K}^{-1} \text{ mol}^{-1}$), whereas the highest energy channel is a direct bond cleavage ($\Delta S_{1000K}^\ddagger = 32 \text{ J K}^{-1} \text{ mol}^{-1}$). As expected, the branching ratio between the two channels depends dramatically on the internal energy content.

Loss of HF from the 1,1-difluoroethylene cation at low internal energy leads to the fluoroacetylene fragment

Figure 2 Reaction mechanism for the loss of iodine from the *p*-iodotoluene cation, after the work of Lin and Dunbar: Lin CY and Dunbar RC (1994) Time-resolved photodissociation rates and kinetic modelling for unimolecular dissociations of iodotoluene ions. *The Journal of Physical Chemistry* 98: 1369–1375.

ion with a rate constant in the metastable range and a large reverse activation barrier of nearly 1 eV. At higher internal energy, collisional activation experiments and TPEPICO data show that a competitive channel becomes open, leading probably to the fluoroethynylidene cation. This is associated with a decrease in the kinetic energy released to the fragments.

Multistep Fragmentations

A dissociation can very seldom be described as a one-step process starting from a unique potential energy minimum and leading to the fragments via a unique transition state. One or more reversible isomerization steps prior to dissociation have been frequently proposed to interpret experimental data in the framework of a classical kinetic scheme coupled with a RRKM evaluation of the appropriate rate constants. *Ab initio* calculations have revealed the importance of unconventional species like bridged structures and of distonic ions as stable ionic structures. Distonic ions are radical ions for which the ionic site and the radical site are formally separated, like in $^{\bullet}CH_2CH_2OH_2^+$. Furthermore, ion–neutral complexes have been suggested in many instances to play an important role in the dissociation mechanism. The production of HCO^+ from $CH_3OH^{+\bullet}$ at threshold has been shown to proceed via the following multistep sequence:

where both a distonic ion and two ion–neutral complexes (bracketed species) are involved. The typical ion–neutral separation in such a complex is in the 3–5 Å range.

Rearrangements or ion–neutral reactions can take place within this entity. They are favoured at low internal energy, whereas simple cleavages become more probable at higher internal energy. A spectacular ion–molecule reaction within an ion–neutral complex has been discovered by Botter and Longevialle: it results in the transfer of a proton from the D ring to the A ring of a steroid molecular ion.

The decomposition of the propanol cation is a nice example of a concerted investigation by coincidence methods, including selective deuteration, and *ab initio* calculations. Figure 3, adapted from work of Baer and Booze, describes the multistep process involved in the competition between the H loss and H₂O loss channels. Intermolecular isotope effects were studied with partially deuterated propanol cations, CD₃CH₂CH₂OH⁺. A very small isotope effect is observed for the H loss, which, according to the model, is a secondary effect. Water loss, on the other hand, involves a 1, 4-hydrogen shift as an intermediate step. Deuteration brings about a primary isotope effect, characterized by a 0.15 eV increase in the critical energy.

The intermediate steps which have just been mentioned correspond to successive minima of the potential energy surface. What about the transition state? It is not unique either. To find its position is a particularly critical problem if no saddle point appears along the dissociation pathway. As suggested by Bowers and co-workers, two transition states exist in this case, respectively at small and large values of the reaction coordinate. The internal transition state results from the competition between the conversion of kinetic into potential energy and the

decrease of the vibration frequencies as the system moves along the reaction coordinate. The second transition state, which is called the orbiting transition state, is associated with the centrifugal barrier appearing at larger values of the reaction coordinate. The internal transition state is expected to play a significant role at high internal energy, whereas the external transition state governs the dissociation rate at energies closer to the threshold. The experimental observation of this transition state switching is still sought for single-well potential energy surfaces in ionic systems. Other kinds of transition states can also be invoked. A strong curvature of the reaction path brings about a bottleneck in the energetically allowed phase space and thus a decrease of the reaction rate. An avoided crossing between two potential energy surfaces limits also the reactive flux due to a branching between the two electronic states. This latter aspect will be discussed in the next subsection.

Nonadiabatic Reactions

The excited electronic states of the molecular ion which are populated by the ionization process in general decay very rapidly (lifetime of the order of 0.1 ps) to the ground electronic state by internal conversion of electronic energy into vibrational energy. If the electronic ground state does not correlate adiabatically to a given pair of fragments, the production of these fragments requires a transition to a potential energy surface correlating to the appropriate dissociation asymptote, at some stage of the decomposition process. A reaction requiring such an interstate transition is referred to as nonadiabatic.

Figure 3 Multistep reaction pathway for the loss of H and H₂O from ionized propanol. The figure is adapted from a study by Booze and Baer: Booze JA and Baer T (1992) Dissociation dynamics of energy selected propanol ions from a σ -type ion structure. *The Journal of Physical Chemistry* 96: 5715–5719.

Nonadiabatic behaviour is always expected when a competition involves two close-lying dissociation asymptotes, differing only by the location of the positive charge on one or the other fragments. In general, this will always be the case for charge-transfer reactions. The statistical theories can be adapted to accommodate nonadiabatic transitions occurring along the reaction path. Briefly, the non-adiabatic transition probability, that is the probability of switching from one potential energy surface to the other, is introduced as a kind of transmission coefficient in a RRKM-like equation.

The two electronic states involved in a non-adiabatic transition have either the same or a different multiplicity. In the former case, the coupling of the electronic and nuclear motions is involved. If multiplicity changes, the transition is due to the spin-orbit coupling. A recent example deals with the unimolecular loss of singlet H_2 from triplet CH_3O^+ to produce singlet HCO^+ . On the basis of the measurement of intramolecular kinetic isotope effects and *ab initio* calculations, Schwarz and co-workers rejected the usually accepted stepwise mechanism in favour of a mechanism in which loss of H_2 and intersystem crossing are concerted.

Tunnelling

If a reverse activation barrier exists, tunnelling is possible. The probability of tunnelling depends dramatically on the reduced mass. The smaller the reduced mass, the larger the probability. Furthermore, the largest H-D isotope effects are expected to occur near the threshold. This corresponds generally to the metastable time scale, which is the most easily accessible to mass spectrometric experiments. If very large H/D kinetic isotope effects are observed, sometimes larger than 1000, then tunnelling is often proposed as the most probable explanation. To take tunnelling into account in the RRKM equation, a transmission coefficient is introduced. It can be calculated analytically provided an appropriate model is used for the potential energy barrier. The asymmetric Eckart potential is often chosen.

Ab initio calculations performed by different groups on the loss of H_2 from the ethane cation agree that the appearance energy for this rearrangement lies below the top of the barrier. On the other hand, any RRKM calculation neglecting tunnelling leads to a rate constant at threshold larger than 10^8 s^{-1} , which is inconsistent with the metastability of this reaction. RRKM calculations by Weitzel including tunnelling are in good agreement with $k(E)$ measurements by the TPEPICO technique.

The intermolecular kinetic isotope effect $k_{\text{H}}/k_{\text{D}}$ for the loss of HCl or DCl from $\text{C}_2\text{H}_5\text{Cl}^{+\bullet}$ and $\text{C}_2\text{D}_5\text{Cl}^{+\bullet}$ respectively lies between 10^2 and 10^5 . It has been well accounted for by RRKM calculations including tunnelling (Booze and co-workers).

As shown by Lifshitz, Schwarz and co-workers, the methane elimination from the acetone cation proceeds via two successive intermediates, a hydrogen-bridged complex and a ketene-methane ion-neutral complex. The barrier separating these two entities lies 14.2 kJ mol^{-1} above the $\text{CH}_2\text{CO}^{+\bullet} + \text{CH}_4$ asymptote. Tunnelling through this barrier is required to account for the appearance of the $\text{CH}_2\text{CO}^{+\bullet}$ fragment at its thermochemical threshold.

Isolated State Decay

In most ionic unimolecular reactions, internal conversion to the ground electronic state is rapid compared to dissociation. In a few cases, however, evidence has been found of a rapid and specific dissociation process occurring on the potential energy surface of an excited electronic state. When such an 'isolated state decay' occurs, a correlation exists between the branching ratio for the specific channel and the photoelectron spectrum. Ionized difluoroethylenes for example, dissociate statistically below the $\tilde{\text{C}}$ state but this latter state favours strongly the fluorine loss channel.

Future Prospects

A fairly important amount of kinetic data is nowadays available, which in the vast majority of cases have been accounted for by a classical kinetic scheme coupled to a RRKM evaluation of the rate constants involved, possibly including tunnelling. The story is, however, far from being complete.

1. The rate constant is often known only in a limited range so that being able to fit the data to a statistical equation like the RRKM-QET one is not a definitive proof of statisticity by itself. The translational energy distribution of the fragment ions is a complementary piece of information which is more sensitive to any deviation from a purely ergodic situation. Rather few detailed analyses of experimental distributions are available.
2. Nonadiabatic reactions are probably much more widespread than usually thought. In particular the role of spin-orbit coupling in unimolecular chemistry deserves careful investigation. In addition to the experimental component, this raises nontrivial *ab initio* computational problems.
3. The interpretation of kinetic experiments is almost always performed on the basis of a classical kinetic scheme. A quantum approach studying the decay of quasibound states, called resonances, could be more appropriate under given circumstances. Large fluctuations of nearly two orders of magnitude have been found, for example, for the decay rate of state-selected formaldehyde.

$\Delta_f H^\circ[M]$	molecular heat of formation

Neutral Thermochemistry

For neutral organic compounds there are many good determinations of molecular heats of formation, $\Delta_f H^\circ[M]$. These have been carefully selected by Pedley and co-workers over an extended period. The standard heat of formation of an entity, $\Delta_f H^\circ$, is defined as the heat absorbed or released when 1 mole of the species is formed from its constituent elements at 298 K and at 1 atm pressure. This is represented by an equation, for example

The terms in brackets represent the phase in which the reactants and products are stable in their standard state at 298 K and 1 atm pressure (1 cal = 4.184 J).

Although some organic compounds have accurate experimental $\Delta_f H^\circ$ values, the knowledge that $\Delta_f H^\circ$ for homologous organic compounds can be represented as an additive property has resulted in the production of additivity coefficients, the terms which are most closely associated with the work of Benson. The coefficients now available allow one to estimate $\Delta_f H^\circ$ for a very wide range of organic compounds via simple arithmetical calculations. Sufficient data exist for the estimation of many geometric effects such as ring strain energies, geometric isomers, etc.

Ionization Energies and Ionic Heats of Formation, $\Delta_f H^\circ[M^{\bullet+}]$

The $\Delta_f H^\circ$ value for a molecular ion $M^{\bullet+}$ is obtained from the measurement of the ionization energy (IE) of neutral M. The reaction

has

$$\Delta H_{\text{reaction}}^\circ = \text{IE}[M] = \Delta_f H^\circ[M^{\bullet+}] - \Delta_f H^\circ[M] \quad [1]$$

$\Delta_f H^\circ[M]$ is obtained from reference data, from an additivity estimation or, more recently, from high level *ab initio* molecular orbital theory calculations. The IE is derived from an experimental measurement. In eqn. [1] the electron is given an enthalpy of zero (i.e. it is assumed to be stationary). Ionization energies can be obtained from photoelectron spectra or from direct measurement of the ionization threshold using monochromated photons or energy-selected electrons. Whatever method is chosen, the most important factor in determining a molecular IE value is the relative geometry of the molecular ion and the neutral molecule, both in their ground states. The terms vertical IE and adiabatic IE are defined in Figure 1.

If the geometry difference between the molecule and its ion is particularly large then the adiabatic IE (that is necessary for the determination of $\Delta_f H^\circ[M^{\bullet+}]$ in eqn [1]) will be difficult to measure. Photoionization is only a vertical process; electron impact is less so because the approach of the ionizing electron and its effects on the molecule are not instantaneous. For moderate geometry differences, the adiabatic IE can be measured using energy-selected electron beams, as a reasonably well-defined asymptote in the ionization efficiency curve, see Figure 1.

Molecular adiabatic ionization energies are to be found in the NIST database (see Further Reading section) and other reference books.

A number of attempts have been made to produce empirical equations for the estimation of molecular ion enthalpies, notably by Mouvier and co-workers and by Holmes, Fingas and Lossing. The latter is a simple combination of Benson-type additivity terms for the neutral's $\Delta_f H^\circ$ and a reciprocal term that incorporates the IE. This arises from the observation that for homologous molecules their IE values fall linearly with the reciprocal of the ion size, represented as $1/n$, where n is the number of atoms in the molecule. The equation

$$\Delta_f H^\circ[M^{\bullet+}] = A - Bn + (C/n)$$

where A , B and C are derived from experimental data for a given homologous series works well for various organic compounds that contain C, H, O and halogen. The secondary empirical relationship, that IE for homologous molecules are proportional to $1/n$, has proved useful in

Figure 1 Vertical (v) and adiabatic (a) ground state to ground state ionization energies. Upper curves are the potential energy diagrams for two molecules, M_1 and M_2 , and their molecular ions. For M_1 there is no significant geometry change on ionization and v and a have the same value. For molecule M_2 , the geometry of the ion is not the same as that of the neutral and so $v > a$. The lower figure shows the ion onset curves (broken lines) and the vibrational modes accessed in the ion with the lines' length showing their relative importance in the ionization process. Note, the more poorly defined onset for M_2^+ .

many applications where an unmeasured IE needs to be estimated or where an experimental value appears to be anomalous.

The empirical equation of Mouvier is more complex:

$$\log \left[\frac{IE(R^1XR^2) - IE_\infty}{IE_0 - IE_\infty} \right] = 0.106[I(R^1) + I(R^2)]$$

where X is a functional group, R^1 and R^2 are attached alkyl groups, IE_∞ is a constant for each compound type and IE_0 is that for a reference compound. $I(R^n)$ are empirical constants for each R group. The IE values derived and the $\Delta_f H^0$ [ion] values obtained using the appropriate neutral enthalpies provide constant ionic heats of formation.

Perhaps the most important use of all such schemes is their ability to reveal misfits in reference data or to highlight an ion having unusual stabilizing or destabilizing properties.

The $\Delta_f H^0$ values for even-electron ions (i.e. ionized free radicals) can be obtained from direct measurement provided that a clean source of the appropriate free radical can be devised. The most versatile method has been that pioneered by Lossing in which the flash pyrolysis of nitrite esters was used to generate the radicals, for example.

Direct IE measurements by these means remove the uncertainties which arise in appearance energy (AE) measurements (described below).

Appearance Energies

The measurement of the $\Delta_f H^0$ for a fragment ion is an important aid to ion structure determination. The energy change associated with the general equation

is called the appearance energy (AE) (for the fragment ion M_2^+). The simple thermochemical relation, eqn [2], corresponding to this reaction:

$$\Delta H_2^0 = \text{AE}[M_2^+] = \Delta_f H^0[M_2^+] + \Delta_f H^0[M_3^\bullet] - \Delta_f H^0[M_1] \quad [2]$$

is insufficient to describe the full result of the AE measurement for several reasons:

- The reverse reaction may have an energy barrier, E_{rev} , and so the measured AE will exceed the thermochemical minimum for the reaction.
- The measured AE may be too high because dissociation of $M_1^{\bullet+}$ involves a significant kinetic shift. A kinetic shift arises as follows. The time-scale of the experiment for measuring the AE is usually very short, typically 10^{-4} to 10^{-6} s, and so for the unimolecular dissociation of $M_1^{\bullet+}$ ions to achieve rate constants of 10^4 – 10^6 s $^{-1}$ they must contain excess energy above the minimum required for the reaction to proceed. For many dissociations, particularly simple bond cleavages in small ions, the kinetic shift effect is negligible. For dissociations of large ions or molecular elimination reactions, the effect can be appreciable, as much as 0.5 eV. In addition, for small molecular ions which lie in deep potential wells, the large density of states at the dissociation limit may give rise to a significant kinetic shift. A good example is provided by the phenyl halides, where on the μ s time-scale the mean kinetic shift for the simple bond cleavage reaction

is 0.7 eV. Note that if the AE values for fragment ions from *metastable ion* precursors are measured, the limiting observational rate constant reduces to $\sim 10^4 \text{ s}^{-1}$ and the above kinetic shift is halved. Delayed observations, on the millisecond time-scale, reduce the kinetic shift even further.

- (iii) In general, the internal energy of the reactant molecule is taken to be that corresponding to the ambient temperature of the ion source and that of the products is essentially unknown. In photoionization AE measurements, Traeger has supposed that the products are at 0 K, perhaps an unlikely outcome for polyatomic species. Proposing that the products' energy differs little from those of the neutral reactant does not appear to introduce major errors.
- (iv) The caveats regarding $\Delta_f H^0[M_1]$ apply also for $\Delta_f H^0[M_3^\bullet]$, which as a free radical may not have a

well-assigned enthalpy of formation. Indeed, radical $\Delta_f H^0$ values can reliably be obtained from AE measurements when the ionic heat of formation $\Delta_f H^0[M_2^+]$ is well established and $\Delta_f H^0[M_3^\bullet]$ is the unknown. The results of this approach equal those derived from activation energies determined from the kinetics of neutral species' reactions.

- (v) Hidden rearrangements: in many cases the structure of the ion and the accompanying neutral fragment are not in doubt. However, a significant number of molecular ions undergo unpredicted rearrangements before they fragment. If, therefore, there is any doubt as to the structure of the fragmentation products, then appropriate experiments should be performed. Two examples suffice to illustrate the problem: the $\text{C}_2\text{H}_6\text{O}^{\bullet+}$ ion generated by loss of CH_2O from ionized propane-1, 3-diol is neither $\text{CH}_3\text{CH}_2\text{OH}^{\bullet+}$ nor

Figure 2 Plots of $\Delta_f H^0 [\text{ion}]^+$ versus $\log(\text{ion size})$, the latter being represented by n , the number of atoms in the ion. The steep curves show the effect of successive OH substitution in alkyl ions and the shallow curves are for CH_3 substitution therein.

$\text{CH}_3\text{OCH}_3^{\bullet+}$ (molecular ions of the only two stable $\text{C}_2\text{H}_6\text{O}$ compounds) but has the structure $\text{C}^+\text{H}_2\text{CH}_2\text{O}^+\text{H}_2$. This ion behaves as an electrostatically bound water molecule – ethene ion; its $\Delta_f H^\circ$ value is *lower* than that of either of the above two conventional ions and, indeed, is the lowest energy $\text{C}_2\text{H}_6\text{O}^{\bullet+}$ isomer.

The dissociation of ionized methyl acetate appears to be trivial

with the formation of the acetyl ion and a methoxy radical as the products. Astonishingly, the ion is as expected but the lowest energy dissociation of this molecular ion produces the isomeric hydroxymethyl radical, $\text{CH}_2\text{OH}^\bullet$, instead of the predicted $\text{CH}_3\text{O}^\bullet$ species. In this case, profound rearrangements have preceded dissociation.

In summary, AE measurements, although relatively easy to perform, may be difficult to evaluate because of the above uncertainties. However, a reverse energy barrier will often be manifest by the magnitude of the kinetic energy release observed in the metastable peak accompanying the fragmentation. A small kinetic energy release of say <10 meV likely indicates neither a reverse energy barrier nor a significant kinetic shift.

Except for the existence of a reverse energy barrier, most of the above problems are avoided in photoelectron-photoion coincidence experiments, where the dissociation of only internal energy selected species are observed.

Estimation of Ion Enthalpies

It was described above how empirical expressions can be used to estimate $\Delta_f H^\circ$ values for odd-electron (molecular) ions.

No such simple formulae have been derived for even-electron (fragment) ions, but some useful general semi-quantitative relationships have been found. The simplest is that for successive substitution of a single group (e.g. CH_3 , OH, etc.) at a formal charge-bearing site. $\Delta_f H^\circ[\text{Ion}]$ decreases linearly with $\log(\text{ion size})$, the latter usually being represented by the number of atoms in the ion. This is illustrated in **Figure 2** for successive substitution of H by X, beginning with the methyl cation. Note that the OH substitutions (steep lines) and CH_3 substitutions produce linear plots of similar slope.

Charge Density in Ions

It is worth emphasizing that thermochemical data give insights as to the distribution of charge in related ions. Thus, for example, the effect of methyl substitution at carbon in $[\text{CH}_2\text{OH}]^+$ is much greater than for the substitution at oxygen; $\Delta_f H^\circ[\text{CH}_2\text{OH}]^+ = 169 \text{ kcal mol}^{-1}$. $\Delta_f H^\circ[\text{CH}_3\text{CHOH}]^+ = 139 \text{ kcal mol}^{-1}$ [$\Delta(\Delta_f H^\circ) = -30 \text{ kcal mol}^{-1}$], whereas $\Delta_f H^\circ[\text{CH}_2\text{OCH}_3]^+ = 157 \text{ kcal mol}^{-1}$ [$\Delta(\Delta_f H^\circ) = -12 \text{ kcal mol}^{-1}$]. Thus the hydroxymethyl cation (protonated formaldehyde) is better represented as $^+\text{CH}_2\text{OH}$ (a ^+C hydroxy substituted carbocation) than as $\text{CH}_2=\text{O}^+\text{H}$ (an oxonium ion). This is also borne out by the ion's reactivity and its behaviour in ion–molecule complexes.

The effects of, for example, OH substitution at, near and away from a formal charge-bearing site are clearly and significantly different, a good example being provided by the isomeric ions shown in **Table 1**. Note that the heat of formation of the ion, when OH is *not* at the formal charge-bearing site (here the π -system), is governed by the difference in $\Delta_f H^\circ$ values for the neutral alkene and alkenol. When OH is at the charge site, the stabilization effect is much greater.

Proton Affinities

It is predicted that there should be a linear relationship between the proton affinities of homologous molecules and their ionization energies. A simple thermochemical cycle gives

$$\text{PA}[\text{M}] = \text{HA}[\text{M}^+] + \text{IE}[\text{H}] - \text{IE}[\text{M}]$$

If the hydrogen atom affinity (HA) of homologous ions is a constant, then

$$\text{PA}[\text{M}] \approx \text{constant} - \text{IE}[\text{M}]$$

This equation indeed works quite well for homologous alcohols, ethers, carbonyl compounds, amines, etc.

Table 1 The effect of OH substitution at various positions in alkenes and their ions (energies in kcal mol^{-1})

Alkene	$\Delta_f H^\circ[\text{M}]$	$\Delta_f H^\circ[\text{M}^{\bullet+}]$	$\Delta(\Delta_f H^\circ)$	
			Neutral	Ion
$\text{CH}_2=\text{CHCH}_2\text{CH}_3$	0	222	–	–
$\text{HOCH}=\text{CHCH}_2\text{CH}_3$	–42	150	–42	–72
$\text{CH}_2=\text{C}(\text{OH})\text{CH}_2\text{CH}_3$	–43	150	–43	–72
$\text{CH}_2=\text{CHCH}(\text{OH})\text{CH}_3$	–38	181	–38	–41
$\text{CH}_2=\text{CHCH}_2\text{CH}_2\text{OH}$	–36	184	–36	–38
$\text{CH}_2=\text{C}(\text{CH}_3)_2$	–4	209	–	–
$\text{HOCH}=\text{C}(\text{CH}_3)_2$	–45	145	–41	–64
$\text{CH}_2=\text{C}(\text{CH}_3)\text{CH}_2\text{OH}$	–38	176	–34	–33

Electron Affinities

The electron affinity (EA) of a molecule is defined as

$$\text{EA}[\text{M}] = \Delta_f H^0[\text{M}] - \Delta_f H^0[\text{M}^-]$$

Again the problems of adiabatic and vertical values arise. The best values probably are determined by laser photoelectron spectroscopy and laser photodetachment. Both of these methods directly measure a threshold energy for the removal of an electron from the anion. EA values are listed in the NIST inventory of data. In general, electron-binding energies to molecules and radicals are less precisely known than cationic $\Delta_f H^0$ values. In thermochemical calculations, the term 'gas phase acidity' $\Delta_{\text{acid}} H^0[\text{AH}]$ is often employed

$$\Delta_{\text{acid}} H^0[\text{AH}] = \text{BDE}(\text{A} - \text{H}) - \text{EA}[\text{A}] + \text{IE}[\text{H}]$$

where $\text{BDE}(\text{A} - \text{H})$ is the homolytic bond strength ($\text{A} - \text{H}$). Alternatively

$$\Delta_{\text{acid}} H^0[\text{AH}] = \Delta_f H^0[\text{A}^{-1}] + \Delta_f H^0[\text{H}^+] - \Delta_f H^0[\text{AH}]$$

Ion Mobility Spectrometry (IMS) and Mass Spectrometry (MS)

Alexandre A Shvartsburg, Biological Sciences Division, Pacific Northwest National Laboratory, Richland, WA, USA

Published by Elsevier Ltd.

Fundamentals

When subject to electric field of some intensity (E), ions in gases drift with constant speed (v) that is approximately proportional to E with a coefficient termed mobility (K):

$$v = KE \quad [1]$$

Equation [1] is exact at low E , when v is much smaller than the thermal velocities of ions or gas molecules. In this 'low-field' regime, mobility is inversely proportional to the ion-molecule cross section (rigorously, the first-order collision integral), $\Omega^{(1,1)}$, via the Mason-Schamp rule:

$$K = \frac{3}{16} \left[\frac{2\pi(m+M)}{mMkT} \right]^{1/2} \frac{ze}{N\Omega_{\text{avg}}^{(1,1)}} \quad [2]$$

where m and M are the masses of ion and gas molecule, k the Boltzmann constant, T and N the gas temperature and number density, and ze is the ion charge. The subscript 'avg' denotes averaging the cross section over all ion and molecule orientations that are continually randomized by thermal rotation (Figure 1). For monatomic molecules, this condenses to

$$\Omega_{\text{avg}}^{(1,1)} = \frac{1}{8\pi^2} \int_0^{2\pi} d\theta \int_0^\pi d\phi \sin\phi \int_0^{2\pi} d\gamma \quad \Omega_p(\theta, \phi, \gamma) \quad [3]$$

where Ω_p is the cross section in a particular direction set by spatial angles θ , ϕ , and γ .

By eqn [2], mobility is a function of the gas temperature and pressure. To align measurements under different conditions, IMS data are expressed as 'reduced mobilities' (K_0):

$$K_0 = K(N/N_0) \quad [4]$$

where N_0 is the number density in gases at standard temperature (273 K) and pressure (760 Torr) (STP). However, the K_0 values are still temperature dependent via the $T^{-1/2}$ factor in eqn [2] and because the cross section varies with ion-molecule collision velocities in a way set by the interaction potential (Φ). Therefore, only K_0 values at equal temperature are truly comparable. Depending on the depth of Φ relative to the temperature, heating the gas may increase or decrease mobility. As Φ depends on the nature of both collision partners, ions have different mobilities in different gases. Since the changes in mobility as a function of gas identity or temperature depend on the ion, one can modify IMS separations by adjusting those parameters.

Equation [2] permits characterizing ion structures by matching experimental $\Omega_{\text{avg}}^{(1,1)}$ to the values computed for plausible geometries. Such calculations entail propagating statistical ensembles of collision trajectories on an assumed Φ surface and integrating the scattering angle (χ) over all collision impact parameters (b) and relative ion-molecule velocities (v_{rel}):

$$\Omega_p(\theta, \phi, \gamma) = \frac{\pi}{4} \left(\frac{\mu}{kT} \right)^3 \int_0^\infty v_{\text{rel}}^5 \exp\left(\frac{-\mu v_{\text{rel}}^2}{2kT} \right) \times dv_{\text{rel}} \int_0^\infty b[1 - \cos\chi(\theta, \phi, \gamma, v_{\text{rel}}, b)]db \quad [5]$$

This evaluation is simple for repulsive hard-shell interactions but complex and costly for realistic potentials that comprise attractive parts or account for the expanse of electron clouds. Several formalisms approximating Φ with varying fidelity are known, but none performs well for strongly attractive potentials. So nearly

Figure 1 Three random orientations of the C_{36} ring cluster. Adapted from Shvartsburg AA (2008) *Differential Ion Mobility Spectrometry: Nonlinear Ion Transport and Fundamentals of FAIMS*. Boca Raton, FL: CRC Press.

Figure 2 Fundamentals of FAIMS: (a) asymmetric waveforms, the ideal rectangular (dashed line), and practical bisinusoidal (solid line); (b) ion motion driven by the waveform, when the mobility at high E lies above or below that at low E (species A and C, respectively).

all structural elucidation studies by IMS use the helium gas: its atoms have the minimum polarizability and size of all molecules and hence attract ions least and minimize the effect of atom geometry on cross sections.

In stronger electric fields, ions drift faster and v may compare to or exceed the velocities of thermal ion–molecule collisions. In this ‘high-field’ regime, the v_{rel} distribution, and thus the cross section and mobility, become a function of E . This behavior shares an origin with the $K(T)$ dependence discussed above, and similarly, mobility may go up or down at higher E . This is exploited in differential IMS or FAIMS, where the electric field alternates between a shorter segment with high E and a longer segment with lower E of opposite polarity (**Figure 2a**). These segments have equal integrals, and hypothetical ions with constant mobility would oscillate without separation. Real ions with variable $K(E)$ are slightly displaced in each cycle and thus drift with speed proportional to the difference between K in the two segments (essentially, the derivative of $K(E)$ over sampled E range), regardless of absolute mobility (**Figure 2b**). The drift speed also depends on the waveform and maximizes for rectangular profiles, making them optimum for FAIMS analyses. However, rectangular profiles have unphysical vertical slopes, and practical profiles have trapezoidal or other smoothed shapes. The waveforms produced by manipulation of harmonics (e.g., the bisinusoidal derived by adding two harmonics, **Figure 2a**) are particularly convenient. As the values of a function and its derivative are, in principle, unrelated, FAIMS and IMS separations can be highly orthogonal.

The charge distribution on virtually any polyatomic ion is uneven, resulting in a dipole that may be aligned by an electric field. Overcoming random rotation requires the dipole energy that scales with E to exceed thermal energy, meaning a sufficiently high E . For the dipole moment p :

$$E > kT/p \quad [6]$$

Common small ions have $p < 10$ Debye (D), and aligning them at room temperature necessitates $E \sim 1 \text{ MV cm}^{-1}$. As typical E values are $< 10 \text{ kV cm}^{-1}$ in conventional IMS based on absolute mobility and $< 100 \text{ kV cm}^{-1}$ in FAIMS, small and medium-size ions freely rotate in either, and eqn [2] holds. In contrast, protein and other macromolecular ions frequently have $p > 400$ D that permits alignment at $\sim 20 \text{ kV cm}^{-1}$ standard for FAIMS analyzers. Yet larger species with $p \sim 10^3$ – 10^4 D or higher would also align in conventional IMS. With increasing E , the alignment proceeds stepwise from free rotation to hindered rotation to pendular oscillation to locking. Even with partial alignment, some ion orientations are more probable and the averaging in eqn [3] should be weighed. This would usually affect the separation, as the cross section in the plane perpendicular to dipole normally differs from the orientationally averaged quantity (**Figure 3**). As FAIMS measures the difference between mobilities in the high- and low-field segments, the dipole alignment is especially consequential for FAIMS analyses. The alignment issue grows in importance as IMS studies expand to ever-larger biomolecules and nanoparticles.

Further, the IMS paradigm is predicated on the molecular regime where gas molecules engage an ion regardless of each other. Once the ion dimensions approach the mean free path in gas (λ), the dynamics begin transitioning to the viscous flow regime where the foundational formulas of IMS such as eqn [2] lose validity. To avoid that, one can drop the gas pressure to elevate λ . For example, the sizes of some nanostructures and cell components studied by IMS compare to $\lambda \sim 70 \text{ nm}$ for N_2 at STP, but are much smaller than $\lambda \sim 7 \text{ }\mu\text{m}$ at 0.01 bar pressure.

Technological Principles

Whereas all IMS methods separate ions by mobility properties, the conventional and differential IMS rely on the absolute mobility and its field dependence, respectively. The major conventional IMS approaches (drift tube IMS (DTIMS), traveling wave IMS (TWIMS), and differential mobility analyzers (DMA)) are reviewed, and several more are known. Though all sort ions by the K value, the implementation and performance differ.

Drift Tube IMS

This is the original and perhaps the simplest IMS technique, developed in the 1920s. A static electric field is

Figure 3 Projections of albumin (a common protein with $m = 66$ kDa) on three orthogonal planes, in (a) the plane perpendicular to the computed dipole. The cross sections in those orientations and the averaged quantity (in $\text{\AA}^2$), calculated using the EHSS method, are shown. Reprinted with permission from Shvartsburg AA, Bryskiewicz T, Purves RW, Tang K, Guevremont R, and Smith RD (2006) Field asymmetric waveform ion mobility spectrometry studies of proteins: Dipole alignment in ion mobility spectrometry? *The Journal of Physical Chemistry B* 110: 21966. Copyright 2006 American Chemical Society.

established in a gas-filled enclosure (drift tube) by applying a voltage ladder to the electrodes disposed along the axis. Ions are injected into the tube in periodic pulses, spatially dispersed while traversing it, and detected at the terminus; the distribution of arrival times reveals the mobility spectrum (**Figure 4**). In methods coupling IMS to MS or other downstream stages, ions are passed on but subsequent analyses preserve the separation created by DTIMS, as described for the DTIMS-MS hybrid in the section “Applications” DTIMS is operable over a broad pressure range from a few milli-Torr to 1 atm and above; the common regimes are ‘low pressure’ (~ 1 – 10 Torr) and ‘high pressure’ (~ 100 – 760 Torr).

Nearly all DTIMS systems to date have run in the time domain, where ions coming from consequent pulses must not overlap in the tube, permitting unique assignment of the drift time for each ion. This requires the pulsing period (t_p) to exceed the longest possible drift time; hence, achieving resolving power R mandates a pulse width of $t_w < t_p/R$. This means a duty cycle of $\sim 1/R$, or $\sim 1\%$ for reasonable $R \sim 100$, which correspondingly cuts the ion current output by continuous sources such as electrospray ionization (ESI). One path to improved sensitivity is

Figure 4 Arrival time distribution for a mixture of amino acid cations in N_2 . accumulating ions between IMS pulses, thus turning continuous sources into pulsed ones. However, storing relevant ion quantities securely is a challenge: the radio-frequency confinement works in vacuum and at ‘low pressure’ (using electrodynamic ion funnel traps), but not at ‘high pressure.’

The alternative solution is multiplexing, where multiple ion packets are processed by DTIMS concurrently. Though ions from different packets overlap, the mobility information is retrievable by injecting pulses following a defined time sequence and decoding the arriving signal with the inverse transform. Unlike in spectroscopy or time-of-flight (ToF) MS, here the classic simplex sequence fails because diffusion broadens the peaks for all species and the packets of the same species from different injections overlap, producing artifact features on the reverse transform. New sparse sequences inspired by the Hadamard transform have provided faithful DTIMS multiplexing, though with a duty cycle under 50%. Combining the ion accumulation and multiplexing approaches increase the duty cycle to nearly 100%, including in the JMS/MS configuration.

Most DTIMS systems employ stationary buffer gas, but operation with gas flowing opposite to the ion drift has been established. Such counterflow increases the resolving power at equal field intensity by prolonging the separation, but restricts the analysis to ions with mobility above the threshold for which the drift velocity exceeds the flow velocity.

Traveling Wave IMS

The TWIMS method, in conjunction with ToF MS, was recently commercialized in the Synapt system (Waters). As with DTIMS, in TWIMS ions are injected in pulses, dispersed while traversing the tube, and registered at the end. Here E is time dependent: a symmetric potential wave created by switching electrode voltages repeatedly sweeps along the tube at high speed s , pushing ions forward in the direction of its propagation (Figure 5). This happens because ions spend more time on the wave front drifting forward (with the instantaneous velocity v subtracted from s) than on its rear drifting backward

(with v added to s). Thus, the displacement of ions by the passing wave depends on their drift velocities on wave slopes, and thus their mobilities. For separation, the wave must travel faster than ions drift at its steepest slope (i.e., $s > KE_{\max}$, where $E_{\max}$ is the maximum E in the wave): ions with mobility exceeding $s/E_{\max}$ are indiscriminately shoved in front. The mean ion transit velocity over the wave cycle ($\bar{v}$) depends on the wave profile. For a triangular potential with same E at any point:

$$\bar{v} = (KE)^2/s \quad [7]$$

So the dependence of average ion velocity on K and E is quadratic in TWIMS, but linear in DTIMS by eqn [1]. Equation [7] is rigorous only when $s \gg KE_{\max}$: in practice, the ion diffusion and nontriangular wave shapes cause major deviations. Therefore, converting the measured ion transit times into mobilities involves extensive calibrations based on species of known mobility.

Unlike with DTIMS, the resolving power of TWIMS is mobility dependent and thus varies across the spectrum. A roughly constant value is achievable over a certain range, but the practical maximum is ~ 50 , which is inferior to DTIMS.

Another issue in TWIMS is the field heating that may induce dissociation or isomerization of ions, precluding or misleading their characterization. Ions pushed by the electric field collide with gas molecules at above-thermal average velocity, and the translational temperature is raised by:

$$\Delta T = M(K_0 N_0)^2 (E/N)^2 / (3k) \quad [8]$$

Thus, ΔT scales as $(E/N)^2$ and, as ions in a gas bath are thermal, the internal temperature increases by the same amount. In Synapt, the values of E are small, but low operating pressure (typically <10 Torr) makes for high

E/N and, therefore, for substantial heating. One should remember this when employing TWIMS to investigate macromolecular structures.

Differential Mobility Analyzers

Separations based on any molecular parameter can be designed as dispersive techniques (where species are fractionated in space and consecutively detected) or filtering techniques (where species with certain parameter values pass whereas others are destroyed). Dispersive methods that process all ions at once are preferred for global analyses, but discontinuous operation often reduces sensitivity. Filtering methods that select specific ions handle continuous beams and thus tend to be more sensitive in targeted applications. In MS, ions are always sorted by m/z but can be dispersed (e.g., in ToF MS) or filtered (in quadrupole MS). Similarly, ion mobility separations by the value of K can be dispersive (e.g., DTIMS and TWIMS) or filtering such as in DMA.

A DMA separates ions in a gap between two (planar or cylindrical) electrodes using a constant field across the gap and gas flow along it (**Figure 6**). Injected in a continuous beam through an aperture in one electrode, ions traverse the gap and angularly spread depending on the ratio of drift velocity v (and thus K) to flow velocity. Species traveling in a certain direction exit through an aperture in the second electrode downstream of the inlet, and others hit that electrode and are neutralized. Scanning the voltage across the gap reveals the spectrum of species present. DMA units were common in aerosol research since 1970s, but low resolving power (~ 10 – 20 versus >100 feasible in DTIMS) was limiting. Recently, DMA was coupled to MS, and near-sonic gas flows allowed resolving power of ~ 80 for typical ions. These developments extend the utility of DMA to mainstream applications, including complex mixture analyses.

FAIMS

In FAIMS, an asymmetric voltage creates a strong oscillatory field between two electrodes, with ions pulled through the gap by gas flow or a weak longitudinal field. As was described, such a field moves all species across the gap with velocity proportional to the difference between their mobilities at high and low E . For particular species, this motion can be offset by the drift due to the compensation field (E_C) produced by a constant potential superposed on the AC voltage. Those ions remain in equilibrium and pass the gap, whereas others hit either electrode and vanish. Scanning E_C provides the FAIMS spectrum of the present species.

The E_C value can be positive or negative, depending on the sign of the mean $K(E)$ derivative over the sampled E range. With rising E , the mobility may increase, decrease, or initially increase and then decrease, classifying

Figure 6 Scheme of ion filtering in DMA: (a) species 2 passes whereas 1 and 3 are removed; (b) at higher field, species 3 passes whereas 1 and 2 are removed.

Figure 7 Ion classification by the form of $K(E)$ curves: types A, B, and C.

ions as types A, C, and B, respectively (**Figure 7**). The mobility always drops at very high E ; hence, the existence of type A is an artifact of the limited E range in FAIMS. As $K(E)$ reflects the ion–gas molecule potential, a particular ion may belong to different types in different gases. In any gas, the ion type is correlated with mass: the behavior shifts from A to B to C with increasing m . However, the correlation is loose, and FAIMS and MS separations are substantially orthogonal, making FAIMS/MS useful for complex analyses. This combination was commercialized by Thermo Fisher, with FAIMS coupled to a quadrupole or ion trap. The FAIMS dimension is also largely orthogonal to gas chromatography (GC), giving rise to GC/FAIMS instruments developed by Varian and Thermo Fisher.

The FAIMS gap may be planar or curved (cylindrical or spherical). The inhomogeneous field in curved gaps causes ion focusing to (or defocusing away from) the gap median, depending on the ion type and asymmetric waveform polarity. Focusing dramatically improves the ion transmission through FAIMS by suppressing the diffusion and Coulomb repulsion of ions in the gap, but resolution suffers. Since the

focusing power depends on $K(E)$ and thus differs for different ions, the effect distorts the measured spectra. As only some ions focus with either polarity, one may have to scan the same E_C range in curved FAIMS twice. These drawbacks of focusing are eliminated in planar FAIMS devices, such as those available from Sionex or Owlstone. However, effective interfacing of planar FAIMS to MS stages remains work in progress.

Applications

Fast Separation of Complex Mixtures

IMS is physically analogous to electrophoresis in liquids and was called 'gas-phase electrophoresis.' The key advantage of IMS over liquid-phase separations (electrophoretic or chromatographic) is speed. In electrophoresis, the ion drift must be slower than stochastic motion of media molecules. The speed of molecular motion in gases compared to liquids permits IMS to be much faster than capillary electrophoresis (CE): typical mobilities of small ions are $\sim 2 \text{ cm}^2 (\text{Vs})^{-1}$ in N_2 versus $\sim 5 \times 10^{-4} \text{ cm}^2 (\text{Vs})^{-1}$ in water, and the customary timescales of CE and DTIMS with equal $R \sim 100$ also differ by $\sim 10^4$ times ($\sim 1000 \text{ s}$ versus $\sim 50 \text{ ms}$). The flow in liquid chromatography (LC) is driven by pressure rather than by electric field, but the molecular velocities limited by liquid density are close, and separations with the same R also

take $\sim 15 \text{ min}$. Acceleration of separations by four orders of magnitude over conventional methods has made IMS topical for high-throughput proteomic and other biological analyses.

The characteristic timescale of DTIMS analyses ($\sim 10^{-2}$ – 10^{-1} s) is between that of LC ($\sim 10^2$ – 10^4 s) and ToF MS ($\sim 10^{-4} \text{ s}$). This allows 'nested' three-dimensional separations that disperse mixtures consecutively by the retention time (reflecting chemical properties) in LC, mobility in DTIMS, and m/z in MS (**Figure 8**). The cross sections of ions (and hence their mobility within one charge state) are significantly correlated with mass. Hence, DTIMS and MS dimensions are substantially parallel, which reduces the peak capacity of LC/DTIMS/MS below the product of those for constituent stages. The reduction depends on the sample, being less severe for mixtures of dissimilar species than for non-diversified samples such as tryptic peptides. Replacing DTIMS with FAIMS that is more orthogonal to MS mitigates this problem, but the filtering nature of FAIMS means a lower duty cycle. Still, addition of DTIMS with typically $R \sim 100$ usually raises the LC/MS peak capacity by over an order of magnitude. The CE/FAIMS/MS combination was also reported. These platforms have been employed in global proteomic and metabolomic analyses and in targeted applications, primarily in the pharmaceutical context.

Structural Characterization of Nanoscale Materials

Liquid-phase separations do not generally allow a priori characterization of molecular structure because the dynamics in liquids (in electrophoresis) or on surfaces (in chromatography) is so complex that separation parameters could not be related to structure with any accuracy. Though nontrivial, the ion–molecule dynamics in gases (at least helium) is tractable enough to employ eqn [5]. The potential Φ can often be computed using quantum chemistry for small ions, but not for large ones that require structural elucidation. For those, one can stipulate that Φ adopts some analytic form with several parameters adjustable to fit the $K(T)$ curves measured for similar species of known geometry. The common Mobcal software assumes additive pairwise Lennard–Jones potentials between the gas atom and each atom of the ion superposed on the charge-induced dipole interactions with partial charges on the ion. This approach is parallel to semiempirical methods for molecular structure optimization (such as CHARMM), where interatomic forces determined by fitting the properties of known species are transposed to new geometries. The success of this procedure depends on the physical and chemical resemblance between benchmark and test species. For example, the error of mobility calculations using the C–He potential fit for C_{60} fullerene (where carbons are sp^2 hybridized) is $\sim 0.5\%$ for fullerene dimers, but $\sim 5\%$ for carbon chains that are much smaller and feature sp hybridization. Hence, choosing the benchmark judiciously is critical.

This approach was deployed for structural characterization of nanoclusters, mainly those of group IV

elements (carbon, silicon, germanium, and tin) that exhibit rich morphological diversity. In particular, carbon clusters were discovered to evolve from chains to rings to fullerenes and graphite sheets (Figure 9). In clusters of large atoms such as Ge, only a few atoms can interact with a gas atom at once. Then Φ is rather insensitive to the cluster geometry beyond those few atoms and can be approximated as a pairwise hard-sphere potential. This approach, the exact hard-spheres scattering (EHSS) model, greatly accelerates mobility calculations. Semiconductor clusters were found to include blocks absent in the bulk, such as tricapped trigonal prisms. Measurements as a function of gas temperature may uncover isomerization or melting that affect the cluster geometry. For example, DTIMS/MS studies have found that elongated Sn clusters stay solid above the melting point of macroscopic tin. This counterintuitive phenomenon is not exclusive to tin and results from drastic difference between the bonding schemes in clusters and the bulk.

Extracting ion structures from FAIMS separation parameters has not been demonstrated thus far. That would require computing the difference between mobilities for candidate geometries in strong and weak fields, an extreme challenge because that difference is normally just $\sim 1\%$ of the mobility values.

Conformational Analysis of Macromolecules

The tools developed for structural elucidation of nanoclusters also apply to proteins, DNA, and other biomolecules that may adopt multiple conformers. For example, proteins lacking disulfide links are flexible and

unfold (denature) in solution, depending on the temperature and solvent composition that determines the charge state. Characterization of those conformers by DTIMS/MS has expanded knowledge about the tertiary structure of proteins not influenced by solution, providing new insights into the dynamics and kinetics of protein folding (Figure 10). Some proteins (prions) assume multiple conformations *in vivo*: the 'normal' and the deviant that spreads by converting the normal on contact and aggregates, causing neurodegenerative diseases such as Alzheimer's and mad cow disease (BSE) and its human analogs. Exploration of that process using DTIMS has illuminated the prion propagation mechanism, highlighting the role of specific small intermediates on the path to amyloid fibrils.

Another topical problem is the profiling of protein complexes, especially of the heterogeneous kind. Although MS methods can determine their composition and often connectivity, the same units can dock at different sites to form distinct quaternary structures. The geometries of large complexes (cellular machines) such as 'vaults' were characterized by TWIMS or the method called GEMMA (gas-phase electrophoretic mobility molecular analysis) based on DMA.

Though FAIMS presently cannot characterize ion conformers a priori, it can pre-separate them for DTIMS analyses in a FAIMS/DTIMS/MS arrangement. Such two-dimensional separations have found more protein conformers than either FAIMS or DTIMS alone, including multiple unfolded geometries for highly charged ions (Figure 11). Proteins of molecular mass under ~30 kDa are C-type ions in FAIMS, and up to ~10

Figure 11 FAIMS/DTIMS map for cytochrome c (15+) reveals at least five isomers hidden under the single DTIMS feature for 'unfolded' geometries. isomers can normally be separated. Heavier proteins tend to comprise both B- and C-type ions, with the separation space expanded by an order of magnitude (presumably because of dipole alignment). This potentially enables

FAIMS and FAIMS/DTIMS to distinguish many more conformers for large macroions. Ion activation between FAIMS and DTIMS stages (e.g., by field heating in an ion funnel) permits mobility analysis of the products of dissociation or isomerization of selected isomers – the IMS analog of tandem MS. A similar capability, including IMS³ that is parallel to MS³, has been provided by stacking DTIMS stages with funnel interfaces.

Field Detection of Airborne Chemicals

An IMS separation has a lower resolving power than quadrupole or ion-trap MS, except for ToF MS. However, unlike MS technologies that require vacuum pumps, IMS methods can employ ambient pressure. Hence, IMS devices, especially FAIMS where ions oscillate in a constrained space, are cheaper and easier to miniaturize and operate than MS systems. This renders IMS a natural platform for field analyses of simple samples, such as airborne vapors.

Since 1980s, handheld DTIMS and FAIMS analyzers manufactured by Smiths Detection, GE, and others have been used by militaries and security agencies worldwide to warn of chemical warfare agents and explosive traces (**Figure 12**), and portals for screening passengers and luggage are now ubiquitous in airports. Similar devices are used in industry for gas purity control. Another direction of current interest is surveying the metabolites in human breath as this might have broad diagnostic utility. The central deficiency of stand-alone IMS is limited resolution that often causes false identifications. This problem has been ameliorated by addition of another separation stage in GC/FAIMS or FAIMS/DTIMS arrangements.

Mass spectrometry has played a dominant role in measurements of ion–molecule reactions. These measurements have had broad impact, in both fundamental and applied areas of science. For example, they have provided extensive thermodynamic information about ions and molecules including standard enthalpies of ion formation and the electron affinities, ionization energies and proton affinities of neutral molecules. They have found important applications in analytical and biomedical mass spectrometry and in plasma chemistry. In physical-organic chemistry they have provided fundamental insight into the intrinsic efficiencies of ion–molecule reactions with analogues in solution (e.g. proton transfer (acid–base), nucleophilic substitution (S_N2) and metal–ion coordination reactions) and into the influence of solvation on these efficiencies. Also, they have provided a deeper understanding of the chemistry of the earth's ionosphere and the ionospheres of other planets, of chemical synthesis in interstellar and circumstellar clouds, of flame chemistry, of radiolysis and of ion-induced polymerization.

Ion–Molecule Reaction Measurements

Ion–molecule reactions have been studied using a large variety of mass-spectrometric techniques for over 4 decades over a large range in pressure and temperature.

Low pressure (from $\sim 10^{-5}$ to 10^{-7} torr) measurements have been performed with Fourier transform (FT) and ion-cyclotron resonance (ICR) mass spectrometers and with ion traps. Moderate pressure (from 0.1 to 5 torr) techniques used to investigate ion–molecule reactions include high-pressure mass spectrometry, the flowing afterglow (FA) technique, the selected-ion flow tube (SIFT) technique and the variable-temperature selected-ion flow-drift tube (VT-SIFDT) technique. The latter technique operates over a

temperature range from 85 to 550 K and at average kinetic energies up to at least 1 eV. Measurements at atmospheric pressure have been restricted largely to ion mobility spectrometry and flame-ion mass spectrometry. The latter provides data in the high-temperature range from 1800 to 2400 K. Measurements at temperatures below 160 K have been achieved in a cooled Penning trap, a drift tube and a flow reactor that utilizes cooling by adiabatic expansion. A free jet-flow reactor has been employed to study ion–molecule reaction rate coefficients at temperatures as low as 0.3 to 30 K.

Rates of Ion–Molecule Reactions

Reactions between ions and molecules are among the fastest chemical reactions known. This is because the electrostatic interaction between the charge on the ion and the polarizable (or polar) molecule draws these reactants together at long range. Furthermore, the resulting interaction energy at short range is often sufficiently large to overcome intrinsic energy barriers to chemical change. As a consequence, exothermic ion–molecule reactions often proceed very rapidly at room temperature *at the capture rate*, without an activation energy. This is in sharp contrast to molecule–molecule reactions that normally involve an activation energy. Generalized profiles for the dependence of reactant energy on the reaction coordinate for ion–molecule and molecule–molecule reactions are shown in **Figure 1**. Ion–molecule reactions are often best described by a double-minimum, rather than a single-minimum, potential energy profile.

The reaction rate coefficient, k_r , for an exothermic ion–molecule reaction proceeding without an activation energy is equal to the capture or collision rate coefficient, k_c , which is typically $\sim 1 \times 10^{-9} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$. This is some one to two orders of magnitude larger than that for an exothermic molecule–molecule reaction proceeding without an activation energy. Several theories are available that allow calculation of the capture or collision rate coefficient, k_c , for an ion–molecule collision. According to the most popular theory, the ‘average dipole orientation’ (ADO) theory, the magnitude of k_c is determined by the physical properties of the reactants: the polarizability, α , and permanent dipole, μ_D , of the

Figure 1 Generalized profiles for the dependence of reactant energy on the reaction coordinate for ion–molecule and molecule–molecule reactions. IE and RE represent ionization energy and recombination energy, respectively. Some ion–molecule reactions are better represented by a single- rather than a double- minimum potential.

reacting molecule, the charge on the ion, q , and the reduced mass, μ , of the colliding reactants. The collision-rate coefficient k_c can be calculated using ADO theory from the following equation:

$$k_c = \frac{2\pi q}{\mu^{1/2}} \left[\alpha^{1/2} + C\mu_D \frac{2^{1/2}}{(\pi k_B T)^{1/2}} \right]$$

where C is a correction factor that is a function of α and μ_D , and k_B is Boltzmann's constant. The ratio of the reaction rate coefficient to the collision rate coefficient, k_r/k_c , is a measure of reaction probability per collision or reaction efficiency. Although many exothermic ion–molecule reactions proceed with unit reaction probability at room temperature, others exhibit reaction probabilities much less than unity.

Temperature/Kinetic Energy Dependence

Ion–molecule reactions that are rapid and efficient at room temperature frequently remain rapid as the temperature of the reactants is varied and follow the temperature dependence of the collision rate. Slow reactions at room temperature almost always increase in rate with decreasing or increasing temperature or kinetic energy (see **Figure 2**). This can be understood in terms of the double-minimum potential shown in **Figure 1** and the following reaction mechanism:

As the reactants approach each other they are attracted by electrostatic ion–induced dipole and ion–dipole forces

Figure 2 Rate coefficients for the reaction of O_2^+ with methane measured as a function of average kinetic energy at several temperatures in a variable-temperature selected-ion flow drift tube (VT-SIFDT). Also shown are data taken with a high-temperature flowing afterglow (HTFA) and a drift tube. Reproduced with permission from Viggiano AA and Morris MA (1996) *Journal of Physical Chemistry* 100: 19227–19240.

and form the ‘entrance channel’ complex $(AB)^{+*}$. Further advance along the minimum potential energy path ultimately leads to an increase of potential energy due to bond redistribution. Then the complex exits along the ‘product channel’ and finally dissociates into products. The two potential energy minima (or ‘wells’) are separated by a barrier that controls the overall reaction efficiency, even though the barrier often lies below the initial energy of the reactants. A rate of dissociation back to reactants that decreases more rapidly with decreasing temperature than the rate of the dissociation of $(AB)^{+*}$ into products leads to an increase in overall rate with decreasing temperature. An increase in rate at higher temperatures often results from the emergence of new vibrational, electronic or chemical channels.

Endothermic ion–molecule reactions and ion–molecule reactions with an activation energy have been examined over a wide range of the kinetic energy of the reactant ion (from ~ 0.1 to 600 eV in the laboratory frame). They exhibit a reaction threshold with increasing ion kinetic energy, rapidly increase in reaction rate and then slow down again at higher kinetic energies (see **Figure 3**). An analysis of the kinetic energy dependence of the reaction cross section can provide thermodynamic information about the reacting ions and neutral molecules.

Rotational and translational energy have been found to be equally effective in driving endothermic reactions. For exothermic reactions large rotational effects appear mainly when one or both of the reactants have a large rotational constant. Vibrational effects are more varied: in some reactions vibrational excitation in the anticipated reaction coordinate can strongly affect reaction probability.

Figure 3 Observed variations of product cross sections with translational energy in the centre-of-mass frame of reference (lower scale) and the laboratory frame (upper scale) for reactions of cyclopropane with Ni^+ . Reaction type	
Electron (charge) transfer	$\text{A}^\pm + \text{B} \rightarrow \text{B}^\pm + \text{A}$
Proton transfer	$\text{AH}^+ + \text{B} \rightarrow \text{BH}^+ + \text{A}$
	$\text{A}^- + \text{BH} \rightarrow \text{AH}^\pm + \text{B}^-$
H-atom transfer	$\text{A}^\pm + \text{BH} \rightarrow \text{AH}^\pm + \text{B}$
R^+ transfer	$\text{AR}^+ + \text{B} \rightarrow \text{BR}^+ + \text{A}$
Nucleophilic displacement	$\text{A}^- + \text{RX} \rightarrow \text{AR} + \text{X}^-$
Bond redistribution	$\text{AB}^\pm + \text{C} \rightarrow \text{AC}^\pm + \text{B}$
Radiative association	$\text{A}^\pm + \text{B} \rightarrow \text{AB}^\pm + h\nu$
Collisional association	$\text{A}^\pm + \text{B} + \text{M} \rightarrow \text{AB}^\pm + \text{M}$
Switching	$\text{A}^\pm + \text{B} + \text{C} \rightarrow \text{A}^\pm + \text{C} + \text{B}$
Associative detachment	$\text{A}^- + \text{B} \rightarrow \text{AB} + \text{e}$

Types of Ion–Molecule Reaction

Reactions between ions and molecules can lead to a variety of consequences ranging from the simple transfer of an electron between an ion and a molecule to the nominal transfer of a large molecular fragment accompanied by extensive chemical bond redistribution in both the molecule and the ion. Table 1 summarizes various types of ion–molecule reaction that have been investigated involving singly charged ions, but many also have been observed with multiply charged ions.

Electron-Transfer Reactions

Electron transfer between ions and molecules at thermal energies is subject to energy resonance and Franck–Condon effects. When small ions are involved, electron

transfer is generally inefficient unless there exists a near-resonance between an energy level of the product ion and an available recombination energy of the reactant ion. In addition there must be large Franck–Condon factors connecting the upper and lower states involved in the transition. Energy resonance is necessary, but not always sufficient. For electron-transfer reactions involving triatomic or polyatomic species, the density of states is much larger so that an energy match and Franck–Condon requirement can almost always be obtained. Vibrational-energy dependence is often observed in electron-transfer reactions presumably due to energy resonance and Franck–Condon effects. Low energy electron-transfer collisions often produce products with large amounts of internal energy that can lead to the dissociation of the product ion. The dissociation products provide a signature of the reactant molecule so that electron transfer is useful in the analysis of gases by chemical ionization mass spectrometry. Electron transfer with multiply charged ions leads to charge separation according to the following reaction:

Such reactions involve a ‘reverse activation energy’ resulting from the Coulombic repulsion between the product ions and as a consequence exhibit a delayed onset.

Proton-Transfer Reactions

Proton transfer, either from a protonated molecule to a neutral molecule or from a neutral molecule to a negative ion, often proceeds at or near the collision rate when exothermic (see Figure 4). When the exothermicity is large, internal energy appearing in the protonated product may be sufficient to cause dissociation with the loss of one or more neutral fragments. Thus, as was the case with dissociative electron-transfer reactions, the product ions again provide a signature of the reactant molecule so that these reactions also are useful in the analysis of gases by chemical ionization mass spectrometry. Virtually any molecule can be chemically ionized with an appropriate proton donor and often this is possible with high efficiency and selectivity. Solvation can influence the rate of proton transfer as is illustrated in Figure 5, but proton transfer generally remains fast until solvation renders the reaction endothermic. There is a growing interest in the ion chemistry of multiply protonated biological ions such as multiply protonated peptides and proteins. Proton transfer from multiply protonated cations may occur according to the following reaction:

Figure 4 A correlation between the efficiency of proton transfer, k_{exp}/k_0 , and its overall change in enthalpy, ΔH° , at room temperature. The measurements were taken using the flowing-afterglow technique. Reproduced with permission from Bohme DK (1981) *Transactions of the Royal Society of Canada* 19: 265–284.

Again, a ‘reverse activation energy’ is involved in such reactions as a consequence of the Coulombic repulsion between the product ions.

H-atom and R^+ Transfer and Bond Redispersion Reactions

Successive H-atom transfer reactions can lead to the hydrogenation of unsaturated positive or negative ions. They find importance, for example, in the conversion of atomic ions to hydrogenated poly-atomic ions in interstellar clouds rich in molecular hydrogen. There appears to be no systematic or easy way to predict the efficiency of such ion–molecule reactions other than to say that hydrogen-atom transfer is rarely observed when electron-transfer or proton-transfer channels are exothermic. Similar comments apply to the transfer of larger R^+ species and more general bond redispersion reactions.

Nucleophilic Displacement Reactions

Nucleophilic displacement reactions, reactions that formally also involve the transfer of R^+ , have been explored in great depth in the gas phase with the majority of available mass spectrometric techniques. In part this has

Figure 5 Observed variations with the number of water molecules in the rate coefficient for proton-transfer reactions between hydrated hydronium ions and various molecules B at room temperature. The measurements were taken using the flowing-afterglow technique. Adapted with permission from Bohme DK, Mackay GI, and Tanner SD (1979) *Journal of the American Chemical Society* 101: 3724–3730.

been because of the importance of S_N2 reactions in solution chemistry and their extreme sensitivity to solvent, both in solution and in the gas phase. Unsolvated S_N2 reactions are characterized by double minima in the reaction energy profile as shown in **Figure 1** and the following reaction mechanism:

The central barrier in the double-minimum potential energy profile, a Walden-inversion transition state, may lie above or below the initial energy of the reactants. The rate coefficients for S_N2 reactions show a slight negative temperature dependence.

Gas-phase measurements also have provided information on the dependence of reaction efficiency on the stepwise molecular solvation of the nucleophile A^- in reactions of the following type, where X can be a halogen atom, $R = \text{CH}_3$ and S a solvent molecule:

Such reactions are also characterized by double minima in the reaction-energy profiles. Because of the lower stabilization of the charge-delocalized transition state relative to the charge-localized reactant and product ions,

Figure 6 Observed variations with the number of solvent molecules in the rate coefficient for nucleophilic-displacement reactions between various solvated nucleophiles and methyl chloride at room temperature. The measurements were taken using the flowing-afterglow technique. Reproduced with permission from Bohme DK and Raksit AB (1984) *Journal of the American Chemical Society* 106: 3447–3452.

these profiles converge to a single-maximum profile typical for S_N2 reactions in solution as the number of solvent molecules on the reactant and product ions is increased. Gas-phase measurements of the influence of stepwise solvation on reaction efficiency have shown that solvation by even one or two molecules can reduce the specific rate for nucleophilic displacement precipitously (see **Figure 6**). Retention of all the solvent molecules in the product ion appears to be the exception rather than the rule. Limited measurements indicate that increasing solvation increases the magnitude of the negative temperature dependence.

Association Reactions

Association reactions lead to the growth of an ion through the formation of new bonds ranging from weak electrostatic to strong covalent bonds. For example, association reactions may lead to the solvation of an ion by weak electrostatic or hydrogen bonding, to ion ligation involving bonds of intermediate strength, or even to strong chemical bond formation. Two steps are required for association as shown below: the formation of an intermediate excited adduct ion $(AB)^{\pm*}$ followed by its de-excitation.

Radiative association occurs when the intermediate becomes stabilized by the emission of a photon ($h\nu$), usually in the infrared spectral region. Collisional association results when the intermediate is stabilized by collision with a third molecule M. Although radiative association is a bimolecular and therefore second-order process, intermolecular collisional association is third-order at low pressures and becomes second-order at high pressures when the frequency of collisions with M exceeds the frequency of the unimolecular dissociation of the intermediate ion $(AB)^{\pm*}$. The rate coefficient for collisional association exhibits a *negative* temperature dependence. Also, FT-ICR measurements have shown that the rate coefficient for radiative association has a strong negative temperature dependence.

Radiative association finds importance in high-vacuum ion-trapping instruments and the low-pressure environments of interstellar space. In contrast, collisional association predominates in high-pressure, low-temperature environments. When they occur *sequentially*, collisional association reactions can play a vital role in gas-phase ion solvation (as occurs naturally, for example, in the earth's lower ionosphere), in ion-cluster formation generally, and in the coordination or multiple derivatization of the type important in organometallic chemistry or in ion-induced polymerization, respectively. The following are examples of ion solvation, ion coordination and ion-induced polymerization, respectively:

In the latter reaction involving a multiply-charged reactant ion, intramolecular charge separation is expected to occur and, in this case, may even act to direct the polymerization away from the surface of C_{60} .

Switching Reactions

Adduct ions formed by radiative or collisional association may be transformed by bimolecular switching reactions in which one solvent or ligand molecule is replaced by another. Such reactions may occur at any extent of solvation or ligation and are usually efficient at room temperature when they are exothermic.

Associative Detachment Reactions

Associative detachment reactions are unique to negative ions. The energy profiles for such reactions involve one

or more curve-crossings between one or more of the attractive potential curves of the reactants and the potential curve for the product AB. AB is formed by the rapid autodetachment of an electron from $(AB)^{\pm*}$ at short interaction distances. Exothermic associative detachment for atomic reagents is inevitably fast. Inhibiting factors can arise for molecular systems.

Sources of Information

For up-to-date accounts in the field of ion chemistry, the reader is directed to volumes in the series *Advances in Gas Phase Ion Chemistry* edited by NG Adams and LM Babcock. For earlier reports on various aspects of ion–molecule reactions see the NATO ASI Series edited by P Ausloos, by P Ausloos and SG Lias and by MA Almoester Ferreira. Another source of earlier information is the *Gas Phase Ion Chemistry* series edited by MT Bowers.

There have been a number of tabulations of rate coefficients for gas-phase ion–molecule reactions that include leading references to individual ion–molecule reactions. For the most part they are restricted to limited areas of interest. They include tabulations of rate constants measured with flow reactors (DL Albritton), rate constants of interest in modelling the chemistry of planetary atmospheres, cometary comae and interstellar clouds (VG Anicich), rate constants for reactions involving organic ions containing only C and H (LW Sieck) and those containing more than C and H (LW Sieck and SG Lias). An early, more general, tabulation has been published by Talroze. The most comprehensive tabulation of rate constants for both bimolecular and termolecular reactions determined up to 1986 has been published by Ikezoe and co-workers.

Motivation and Methods

During the early days in the development and application of mass spectrometry to the analysis of organic molecules, electron ionization (EI) was the only ionization method available. Today, many other ionization techniques are available for the analysis of large (bio)molecules, but EI remains a popular method for the ionization of organic molecules that are not too involatile; it is, for example, the method of choice for identifying components in complex mixtures using the powerful technique of gas chromatography–mass spectrometry (GC-MS) in conjunction with fast searches in large EI spectral databases. Although EI produces both positively and negatively charged ions, usually only the singly charged positive ions, which make up conventional EI mass spectra, are used for interpretive purposes. It is not surprising, then, that most of the work published on ion structures concerns the properties of singly charged positive ions.

Almost all organic molecules contain an even number of electrons and so removal of an electron by EI leads to a radical cation, $M^{\bullet+}$, the molecular ion. The conventional mass spectrum reflects the competitive and consecutive fragmentations with rate constants $k > 10^6 \text{ s}^{-1}$ of the molecular ion induced by EI. The interpreter's task then is to deduce the structure of the original neutral molecule from the occurrence or absence of ionic fragmentations. Obviously, a good understanding of which ion structures can be formed and how they dissociate is critical to the interpreter's success.

All experimental methods for ion structure elucidation give information only about the ion's constitution or connectivity, that is which atoms are joined together and the probable (formal) locations of charge (and radical) sites. Details of the ion's configuration, such as bond lengths and angles, are not yet accessible to experiment for polyatomic ions. In the mass spectrometer, ions are gaseous isolated species: they are free from solvent molecules and this makes them especially amenable to molecular orbital (MO) calculations. Indeed, the growing synergism between

experiment and theory in gas-phase ion chemistry has greatly facilitated our understanding in this area. State-of-the-art *ab initio* MO calculations can be as accurate as experiment and as often as not disagreements that emerge are solved by reinterpretation of the experimental data.

The most important methods for ion structure determination are:

- Ion dissociation characteristics obtained by tandem mass spectrometry: both unimolecular, as observed in the metastable ion (MI) mass spectrum and collision-induced, as observed in the collision-induced dissociation (CID) mass spectrum.
- Reactivity, as studied by ion–molecule reactions.
- Ion thermochemistry, that is heat of formation (ΔH_f) data obtained by ionization energy (IE) and appearance energy (AE) measurements, often in conjunction with theoretical calculations.

These may be complemented by isotope labelling experiments, a time-honoured method of unravelling fragmentation mechanisms. With these methods, ions of different internal energies and ion lifetimes are sampled. MI characteristics, as obtained with a sector mass spectrometer, reflect ions that decompose in a field-free region with a narrow range of internal energies just above the threshold for decomposition, $\sim 10 \mu\text{s}$ after their formation. CID mass spectra, also measured with a sector mass spectrometer, and ion–molecule reactions as studied in an ion cyclotron resonance (ICR) cell involve non-decomposing ions with internal energies up to the lowest threshold for decomposition; these ions have lifetimes $> 10 \mu\text{s}$ and $> 1 \text{ ms}$, respectively. Finally, ΔH_f data and MO calculations characterize ions in their electronic and vibrational ground states having, in principle, infinite lifetimes. These different techniques sample ions of different internal energies and lifetimes and, depending on the heights of possible isomerization barriers, they may also sample ions of different structure.

Isomerization of Solitary Ions

Structure elucidation of an organic ion may be rendered difficult by isomerization reactions; this is especially true for the low-energy (metastable) ions. This is illustrated in **Figure 1** for the isomeric ions ABC^+ and ACB^+ whose

Figure 1 Schematic potential energy diagrams showing the relationship between the heights of isomerization barriers and observed products.

dissociations of lowest energy requirement from the unrearranged species lead to AB^+ and AC^+ , respectively.

In **Figure 1a** the isomerization barrier is higher than either dissociation threshold and the isomeric ions will yield different ion products in their mass spectra, so that differentiation is possible on the basis of MI spectra alone. In the case of **Figure 1b** the isomerization barrier is lower than either dissociation threshold and now, prior to dissociation, ions ACB^+ and ABC^+ interconvert. As a consequence, prior to dissociation, the metastable ions will consist of an equilibrium mixture $ACB^+ \rightleftharpoons ABC^+$ that will choose the exit channel of lowest energy, namely to AB^+ . In this case the isomers will yield identical MI spectra. Ions with energies below the transition state for isomerization will have retained their original structure, but these do not dissociate. These ions can be induced to decompose by collisional activation with an inert gas, such as helium, to dissociation products of higher enthalpy, resulting in the CID mass spectrum. These dissociations take place rapidly ($<0.1 \mu\text{s}$) and so interconversion $ACB^+ \rightleftharpoons ABC^+$ will be slow by comparison and the isomers can be differentiated on the basis of their respective CID spectra. The situation pertinent to ion ACB^+ in **Figure 1b** is frequently observed; because they dissociate slowly, metastable ions can undergo

more or less extensive rearrangement reactions to form the most 'economical', but usually non-structure-characteristic, set of products. In CID ('sledge-hammer' approach), the energized species fragment rapidly and so more of the structure-characteristic direct bond cleavages are seen. Finally, the isomerization barrier can be intermediate between the dissociation levels of $AB^+ + C^\bullet$ and $AC^+ + B^\bullet$. In this case ACB^+ isomerizes slowly to ABC^+ which then fragments rapidly. Now the metastable ions will yield the same products but with different internal energies and kinetics. In particular, the kinetic energy released (T value) upon dissociation will be larger for ACB^+ , resulting in broadening of the metastable peak.

Usually CID experiments serve to increase the internal energy of the ions, which then fragment. Under certain conditions, however, such collisions may lead not only to dissociation but also to association. Thus collisions of $C_{60}^{+\bullet}$ with He at high translational energies ($\sim 3 \times 10^4 \text{ m s}^{-1}$) lead to the capture complex $C_{60}\text{He}^{+\bullet}$. This complex survives a neutralization-reionization (NR) experiment, showing that the ionic and neutral complexes have an endohedral structure $\text{He}@C_{60}$. Complexes containing two noble-gas atoms have also been prepared by collision experiments.

Ion Structures

The molecular radical cation, an odd-electron ion, can dissociate in two basic ways. It can undergo a direct homolytic cleavage to produce an even-electron ion and a radical, or it can produce another odd-electron ion by multiple cleavage (as in a cyclic compound) or via rearrangement (as in the McLafferty rearrangement).

Even-Electron Ions

Ionized Radicals

Even-electron ions are formed by loss of a radical from the molecular ions or by addition of a reagent ion to a molecule in an ion-molecule reaction. Most, but not all, even-electron ions formed by dissociative ionization can be viewed as ionized radicals. Such species may be stabilized by resonance or aromaticity. Thus $C_3H_5^+$ ions are abundant ions in many mass spectra, even in cases where the C_3H_5 substructure is not present in the original molecule, and this can be attributed to stabilization by resonance: $\text{CH}_2=\text{CH}-\text{CH}_2^+ \rightleftharpoons ^+\text{CH}_2-\text{CH}=\text{CH}_2$. Similarly, the $C_7H_7^+$ ion, m/z 91, is a ubiquitous peak in the mass spectra of aromatic compounds. Elegant ^{13}C labelling experiments performed in the 1950s have shown that this species in the spectrum of toluene and substituted aromatics is not the expected benzyl ion, $C_6H_5\text{CH}_2^+$ (even though allylically stabilized) but rather the thermodynamically more stable (by $\sim 40 \text{ kJ mol}^{-1}$) cyclic tropylium ion. The reverse situation holds for

radicals; here the benzyl structure is the more stable one. The tropylium ion obeys Hückel's $4n + 2$ rule ($n = 1$) on aromaticity, whereas the tropyli radical does not, and indeed it was Hückel who predicted 70 years ago that the cation should enjoy considerable stability. A similar, but more dramatic, situation occurs for the C_3H_3 structures. Here, for the neutrals, the cyclopropenyl radical is $\sim 96 \text{ kJ mol}^{-1}$ less stable than the propargyl radical, $\cdot\text{CH}_2-\text{C}\equiv\text{CH}$, whereas, for the ions, the cyclopropenium ion ($n = 0$) is the more stable isomer (by 105 kJ mol^{-1}). For the cations, the large destabilization due to ring strain is more than offset by the energy gain due to aromaticity. These examples serve to illustrate an important phenomenon in mass spectrometry: upon ionization a stability reversal of isomeric structures may take effect. This becomes particularly important for odd-electron ions (see below).

The $C_2H_3O^+$ system is one of the earliest examples where experiment and theory have gone hand in hand to produce a detailed description of the potential energy surface. Four stable $C_2H_3O^+$ ions have been generated and identified by MI, CID and isotope labelling experiments and all are calculated by theory to be stable J_s species. These are (with relative calculated ΔH_f values in kJ mol^{-1} in parentheses):

In particular the isomer $\text{CH}_3-\text{O}^+=\text{C}$ presented an experimental challenge, but after theory predicted it should be stable, it was subsequently made. Not surprisingly, the most stable ion, the acetylium ion $\text{CH}_3\text{C}=\text{O}^+$, is the base peak in the mass spectra of methyl ketones. As shown by CID experiments, the ion is also abundantly formed from radical cations that do not contain the acetyl substructure, for example from ionized vinyl ethers, $\text{CH}_2=\text{C}(\text{H})\text{OR}^{\cdot+}$, which do not produce the intrinsically unstable α -formylcarbenium ion $^+\text{CH}_2\text{C}(\text{H})=\text{O}$ via a simple bond-breaking reaction but rather $\text{CH}_3\text{C}=\text{O}^+$. Such 'pseudo-simple cleavage reactions' – which proceed via a 'hidden' hydrogen migration in the molecular ion – often occur, and if they are not recognized for what they are, various erroneous conclusions may be drawn from the experiments. This is exemplified by the behaviour of the dimethyl sulfoxide (DMSO) radical cation, $\text{CH}_3-\text{S}(=\text{O})\text{CM}_3^{\cdot+}$, which is a case par excellence of the situation sketched in **Figure 1b**, where ACB^+ represents the DMSO radical cation. Loss of $\cdot\text{CH}_3$ had always, quite reasonably, been viewed as a direct bond-cleavage reaction to produce $\text{CH}_3\text{S}=\text{O}^+$, and indeed CID experiments on the product ions formed in the ion source (i.e. those ions formed

at relatively high internal energies) showed that this is indeed the case. From AE measurements a $\Delta H_f = 736 \text{ kJ mol}^{-1}$ was derived for the product ions and, logically then, this value was proposed to correspond to the structure $\text{CH}_3\text{S}=\text{O}^+$. However, it followed from CID experiments on the metastably generated product ions (i.e. those ions formed at lower internal energies, corresponding more closely to the AE measurements) that these ions did not have the $\text{CH}_3\text{S}=\text{O}^+$ connectivity, but rather the carbenium structure $^+\text{CH}_2-\text{S}-\text{OH}$, formed via a low-lying ('hidden') 1, 3-H shift in the molecular ions, yielding the intermediate $\text{CH}_2=\text{S}(\text{OH})\text{CH}_3^{\cdot+}$ ion, ABC^+ in **Figure 1b**, and the measured ΔH_f was now assigned to the structure $^+\text{CH}_2-\text{S}-\text{OH}$. Interestingly, these CID experiments were inspired by the *ab initio* MO calculations which correctly predicted that $\text{CH}_2=\text{S}^+\text{OH}$ should have a lower ΔH_f than $\text{CH}_3\text{S}=\text{O}^+$ (by 84 kJ mol^{-1}) in sharp contrast to the carbon analogues $\text{CH}_2=\text{C}^+\text{OH}$ and $\text{CH}_3-\text{C}=\text{O}^+$ (see above). In contrast to ketene, $\text{CH}_2=\text{C}=\text{O}$, where protonation takes place at the carbon to produce the stable structure $\text{CH}_3\text{C}=\text{O}^+$, the protonation of sulfine $\text{CH}_2=\text{S}=\text{O}$, takes place at the oxygen to produce $^+\text{CH}_2-\text{S}-\text{OH}$.

Proton-Bound Molecule Pairs

Even-electron proton-bound molecule pairs ($\text{M}_1 \cdots \text{H}^+ \cdots \text{M}_2$) can conveniently be made by ion–molecule reactions and their properties (for example, bond dissociation energies) can be obtained by ICR-based experiments. Such experiments on symmetric ($\text{M} \cdots \text{H}^+ \cdots \text{M}$) proton-bound dimers and asymmetric ($\text{M}_1 \cdots \text{H}^+ \cdots \text{M}_2$) proton-bound molecular pairs indicate a remarkable constancy in hydrogen bond energies. It appears that symmetric proton-bound dimers have hydrogen bond energies of $130 \pm 10 \text{ kJ mol}^{-1}$ and so ΔH_f of a proton-bound dimer is given by $\Delta H_f = \Delta H_f[\text{MH}^+] + \Delta H_f[\text{M}] - 130$; for asymmetric proton-bound molecule pairs, the hydrogen bond energy depends on the difference in proton affinities (PA) of the bases involved, and for the case $\text{PA}[\text{M}_1] > \text{PA}[\text{M}_2]$ the following empirical equation (eqn [1]) applies for their ΔH_f :

$$\begin{aligned} \Delta H_f = & 0.54\{\Delta H_f[\text{M}_2\text{H}^+] + \Delta H_f[\text{M}_1]\} \\ & + 0.46\{\Delta H_f[\text{M}_1\text{H}^+] + \Delta H_f[\text{M}_2]\} - 130 \end{aligned} \quad [1]$$

Thus, the constancy in hydrogen bond energy allows the assessment of ΔH_f of the proton-bound molecule pair, provided that the PA values of M_1 and M_2 are known. Alternatively, the relative PA values of M_1 and M_2 may be assessed from MI experiments of the proton-bound molecule pair using a sector-type instrument: the intensity ratio of the observed M_1H^+ and M_2H^+ in the MI spectrum is a measure of the relative PA values of the molecules M_1 and M_2 .

Odd-Electron Ions

Enol and Related Radical Cations

The McLafferty rearrangement, discovered in 1952, is the only named reaction in mass spectrometry. For 2-pentanone, the reaction is represented by eqn [2].

At first it was thought that the driving force of this reaction was the expulsion of a stable neutral species (such as $\text{CH}_2=\text{CH}_2$) rather than formation of a stable neutral (keto) ionic product, but from subsequent AE measurements it was concluded – and these findings have been amply corroborated – that the product ions had an enol and not the tautomeric keto structure and that, in contrast to the corresponding neutral molecules, enol radical cations are more stable thermodynamically than the keto tautomers. Thus, as with the C_7H_7 and C_3H_3 structures discussed above, enol structures undergo a stability reversal upon ionization; this is illustrated in **Figure 2** for the acetone radical cation and its enol structures.

Because of their enhanced stability, enol radical cations are produced from many compounds (m/z 58 from methyl ketones; m/z 59 from amides; m/z 60 from acids) and they are thus highly structure-characteristic. They provide a rich source for the generation of neutral enols via NR (neutralization – reionization) mass spectrometry. It is found from such experiments that gaseous neutral enols do not isomerize to the more stable keto counterparts, in agreement with results from pyrolysis mass spectrometry. The class of enol radical cations can be regarded as the harbinger of all ions of unexpected stability (see below). Imidic acids $\text{RC}(=\text{O})\text{NHR}$ (iminols) are the ‘enol’ equivalents of amides, $\text{RC}(=\text{O})\text{NHR}$, and the prototype imidic acid radical cation, $\text{HN}=\text{C}(\text{H})\text{OH}^{+\bullet}$, ionized formimidic acid, has been generated by an appropriate dissociative ionization and identified by CID type experiments. Neutral imidic acids have been proposed as intermediates in the acid-catalysed proton exchange of amides, peptides and proteins, a

Figure 2 Heats of formation of neutral and ionized acetone and its enol showing stability reversal upon ionization. Arbitrary energy scales. $\Delta H_f [\text{CH}_3\text{C}(=\text{O})\text{CH}_3] = -218 \text{ kJ mol}^{-1}$, $\Delta H_f [\text{CH}_3(=\text{O})\text{CH}_3]^{+\bullet} = 720 \text{ kJ mol}^{-1}$.

process of fundamental importance in biochemistry (eqn [3] as opposed to the classical mechanism, eqn [4]). Simple imidic acids have not yet been seen in solution.

NR experiments on ionized formimidic acid showed that a significant fraction of the ions survive neutralization, but, because of interference from neutral products arising from dissociation of the neutralized species, it was not possible, from straightforward NR experiments alone, to assign a unique structure to the neutralized species. Such problems plague other systems too, but neutral identification may still be feasible by selectively analysing the ions recovered after the NR process. Such a NR-CID type of multiple collision experiment is demanding in terms of sensitivity, but nevertheless

perception that 'comparing the reactivity of molecules whose only difference was the electron number was like comparing apples and oranges'. However, if one thing has become clear over the past decade, it is that for gas phase species 'one electron less' can change the chemistry of the species beyond recognition. One of the great discoveries in the 1980s with respect to ion structures was the finding that certain ion structures that did not correspond to those of stable, neutral molecules could nevertheless be very stable, both thermodynamically and kinetically. For example, even a simple radical cation such as $\text{CH}_3\text{OH}^{\bullet+}$ has a stable isomer, $\text{CH}_2\text{OH}_2^{\bullet+}$, the methyleneoxonium radical cation. It has been said, not without exaggeration, that $\text{CH}_2\text{OH}_2^{\bullet+}$ represents a triumph for theory. This is because theory (*ab initio* MO calculations) predicted not only that $\text{CH}_2\text{OH}_2^{\bullet+}$ is more stable than $\text{CH}_3\text{OH}^{\bullet+}$ but also that a large barrier separates these ions; this is shown in **Figure 4a**.

Soon after this prediction was made, the ion was indeed generated and identified. These new species all have in common that, in contrast to conventional isomers, the charge and radical site are formally at separate atoms and as such they are referred to as 'distonic' ions from the Greek 'diestos' and Latin 'distans' meaning 'separate'. If the radical and charge sites are on adjacent atoms such as in $\text{CH}_2\text{OH}_2^{\bullet+}$, the distonic ion can be viewed as an ionized ylid, and as such they are also referred to as 'ylidions'. Distonic ions can also be viewed as charged or protonated radicals, but, because they form a well-defined group of radical cations having characteristic properties, the term distonic ion is a useful one. Distonic ions can be made by judiciously chosen

dissociative ionizations and they can be differentiated from their conventional isomers by MI and CID experiments and by ion-molecule reactions. In **Figure 5** are shown the CID spectra of ionized methanol, $\text{CH}_3\text{OH}^{\bullet+}$ and of the $\text{CH}_2\text{OH}_2^{\bullet+}$ product ion generated by the loss of $\text{CH}_2=\text{O}$ from ionized 1, 2-ethanediol (eqn [6]):

The major dissociation products in the spectrum of **Figure 5b** are $\text{CH}_2^{\bullet+}$ (m/z 14) and $\text{H}_2\text{O}^{\bullet+}$ (m/z 18), and this is compatible only with the $\text{CH}_2\text{OH}_2^{\bullet+}$ structure. This spectrum also reveals that the doubly charged ion $\text{CH}_2\text{OH}_2^{++}$, m/z 16, which can be viewed as doubly protonated formaldehyde, also is a remarkably stable species, despite the large coulombic repulsion of the charges. Such doubly charged ions have been invoked in the field of super-acid chemistry pioneered by Olah, and in solution these species behave as 'super electrophiles'. Thus $^+\text{CH}_2\text{OH}_2^+$ is proposed to be a key intermediate in

Figure 4 (a) Energy diagram for the (unassisted 1, 2-H shift) isomerization $\text{CH}_3\text{OH}^{\bullet+}$ to $\text{CH}_2\text{OH}_2^{\bullet+}$. (b) Energy diagram for the rearrangement $\text{CH}_3\text{OH}^{\bullet+}$ to $\text{CH}_2\text{OH}_2^{\bullet+}$, catalysed by water. Broken lines indicate catalysis by formaldehyde. Energies in kJ mol^{-1} .

the formation of methane from formaldehyde under 'super-acid' conditions.

In the mass spectrometer, many initial molecular ions rearrange to distonic ions by way of a hydrogen shift; these intermediate distonic ions may rearrange further and their reactions involve both the radical and charge sites. Often a charged moiety can easily migrate to the radical site, thereby generating an isomeric distonic ion that in turn can shift its ionized part to the new radical site. Such a sequence can rationalize many otherwise unintelligible reactions. Distonic ions can serve as precursors for the genesis of novel neutral species via the techniques of NRMS. This is illustrated by the generation of the Hammick intermediate [1], a previously unobserved species that has been held responsible for the accelerated decarboxylation of 2-picolinic acid [3] (eqn [7]).

In the mass spectrometer, the molecular ions of 2-picolinic acid eliminate CO_2 and CID experiments indicate that the resulting m/z 79 product ions are the ylidion isomer of pyridine $[1]^{\bullet+}$ and not ionized pyridine $[2]^{\bullet+}$ itself. (The possibility of differing descriptive formalisms, i.e. ylidion or ionized carbene, exists for $[1]^{\bullet+}$.) NR experiments showed that a significant fraction of the ylidions survive neutralization experiments, but because of interference from neutral products arising from dissociation of the neutralized species, it was not possible to assign a structure to the neutralized species. The same problem plagues the formic acid experiment (see above). However, the NR-CID mass spectrum clearly showed that the ylid structure was maintained throughout the NR experiments and so the Hammick intermediate is a stable species on the microsecond timescale.

The first homologue of the methyleneoxonium ion is the distonic ion $^{\bullet}\text{CH}_2\text{CH}_2\text{OH}_2^+$, an isomer of ionized ethanol. *Ab initio* calculations show that the distonic ion is indeed a low-energy species lying $\sim 40 \text{ kJ mol}^{-1}$ beneath ionized ethanol, but also that the C–O bond readily stretches to form the ion–dipole (ion–neutral) complex

$\text{CH}_2=\text{CH}_2^{\bullet+}/\text{H}_2\text{O}$. This species can best be viewed as a positively charged ethene rod to which the water molecule is attached by its dipole, but which can be moved more or less freely along and about the positive rod.

Ion–Neutral Complexes

Traditionally, unimolecular rearrangements of gas-phase (radical) cations have been rationalized in terms of transformations within the covalently bound ion. Increasingly, ion–neutral complexes with a relatively strong electrostatic bond between the incipient fragments are being invoked as intermediates to account for reactions that would otherwise be considered implausible for the intact ion. In an ion–neutral complex the charged and neutral components are sufficiently separated that they show reactivities similar to those expected for the isolated species. Two distinct but related phenomena may be interpreted by means of ion–neutral interactions: the ionic component may react individually by isomerization to a more stable structure (eqn [8a]) or the ionic and neutral species may react with each other, for example by proton transfer (eqn [8b]).

Although the earliest suggestion of a complex-mediated dissociation dates back to 1956, it was not until the early 1980s that it became evident that their involvement in the unimolecular dissociations of odd- and even-electron ions is a widespread phenomenon.

The formation of $\text{CH}_3\text{CH}^+\text{CH}_3$ from the onium ion $\text{CH}_2=\text{O}^+\text{CH}_2\text{CH}_2\text{CH}_3$ is illustrative of isomerization (via a 1, 2-hydride shift) of the cation within the complex followed by dissociation, that is: $\text{CH}_2=\text{O} \cdots ^+\text{CH}_2\text{CH}_2\text{CH}_3 \rightarrow \text{CH}_2=\text{O} \cdots ^+\text{CH}(\text{CH}_3)_2$.

The rearrangement of carbocations, such as the archetypal cation isomerization $^+\text{CH}_2\text{CH}_2\text{CH}_3 \rightarrow ^+\text{CH}(\text{CH}_3)_2$, is a central theme of organic chemistry; the ion in an ion–neutral complex occupies a position between that of the 'bare' ion and that corresponding to the ion in solution. Thus the influence of a single solvent molecule on the rearrangement may be studied.

A classical case of proton transfer between the formal components of a complex concerns the dissociation of steroidal diamines, for example 3,20-diaminopregnane. Here, a long-distance intramolecular and interfunctional proton transfer was proposed to occur in an ion–neutral complex, where upon separation the incipient fragments rotate more or less freely, thus allowing proton transfer between functional groups that originally were distant in the intact molecular ion (eqn [9]).

The maximum stabilization energy (SE) of an ion–dipole complex is achieved when the dipole moment vector points away from the charge; $\text{SE} (\text{kJ mol}^{-1}) = 288 \mu / r^2$, where μ is the dipole moment (in Debye) and r is the distance (in Å) between the point charge and the dipole. For typical values of μ (1.5 D) and r (2 Å) one obtains SEs of $\sim 100 \text{ kJ mol}^{-1}$ with concomitantly smaller values for lower μ . Thus, a strong ion–dipole bond is energetically on a par with a weak covalent bond.

Criteria have been proposed for the intermediacy of ion–neutral complexes, but probably the only good criteria follow from the proposal that such complexes dissociate exceedingly close to threshold. These are (1) very small kinetic energy releases and (2) unprecedented isotope effects. Thus, extreme isotopic fractionation due to differences in vibrational frequencies in the products has been identified in ion–dipole dissociations.

One of the puzzling observations seen in MI spectra is that metastable ions invariably dissociate to the products of lowest enthalpy, despite the obvious mechanistic complexities involved from a conventional point of view; the particular virtue of intermediate ion–neutral complexes is that they facilitate the formation of such low-energy products.

Hydrogen-Bridged Radical Cations

Hydrogen-bridged radical cations are the odd-electron counterparts of proton-bound molecule pairs, $\text{M}_1\cdots\text{H}^+\text{M}_2$. Formally they can be represented as proton-bound molecule–radical pairs ($\text{M}\cdots\text{H}^+\cdots\text{R}^\cdot$), but they are better viewed as H-bridged ion–neutral complexes of the type $\text{MH}^+\cdots\text{R}^\cdot$ or $\text{M}\cdots\text{HR}^{+\cdot}$, with the bridging H closer to the partner of higher PA, where most of the stabilization energy is provided by ion–dipole attractions. The H-bridge furnishes additional

stabilization by about 20 kJ mol^{-1} but its main function is to direct the course of isomerization by allowing a facile proton transfer. Hydrogen-bridged radical cations are harder to make than proton-bound molecule pairs via ion–molecule reactions. They are usually generated by elimination of a stable molecule from a molecular ion, such as loss of CO from ionized β -hydroxypyruvic acid (eqn [10]).

There remains an inherent problem with regard to the identification of a H-bridged radical cation as a stable product ion: the ion may have isomers with closely similar reactivity and dissociation characteristics. This is a well-recognized problem in general, but it becomes particularly acute for H-bridged radical cations because they often dissociate very much like distonic isomers. A case in point is the structure of the ion generated by the loss of C_2H_4 from ionized 1,4-butanediol, $\text{HOCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{OH}^{+\cdot}$. Its dissociation characteristics rule out a simple extrusion reaction yielding $\text{HOCH}_2\text{CH}_2\text{OH}^{+\cdot}$ (ionized 1, 2-ethanediol), but they are compatible with the formation of species comprising vinyl alcohol and water: that is with both the H-bridged ion $\text{H}_2\text{O}\cdots\text{HOC}(\text{H})=\text{CH}_2^{+\cdot}$ and the distonic ions $\text{H}_2\text{O}^+\text{CH}_2\text{C}^\cdot\text{HOH}$ and $^\cdot\text{CH}_2\text{CH}(\text{OH})\text{OH}_2^+$. Analysis of *ab initio* computational results on the isomers, stabilities and conversion barriers in conjunction with energetic information from experiment (AE measurements) resolved the ambiguity and led to the identification of the H-bridged ion.

In some cases, H-bridged radical cations have been generated by ion–molecule reactions. Electron impact ionization of a mixture of H_2O and CO_2 leads to the H-bridged species $\text{HOH}\cdots\text{O}=\text{C}=\text{O}^{\bullet+}$. Although the ion could be differentiated from its covalently bounded isomer ionized carbonic acid, $(\text{HO})_2\text{C}=\text{O}^{\bullet+}$, through its different CID spectrum, the NR mass spectrum provided definitive evidence of its structure. As expected, and in contrast to $(\text{HO})_2\text{C}=\text{O}^{\bullet+}$, the H-bridged species does not survive neutralization and dissociates completely to CO_2 and H_2O .

Hydrogen-bridged radical cations, like ion–neutral complexes, consist of two separate entities and as such they may be considered the smallest type of clusters. Dimer radical cations $\text{M}_2^{\bullet+}$ constitute an interesting class of complexes within the mainstream of cluster chemistry. They can be made by ligand exchange reactions at low pressures in an FT-ICR cell. Noble gas dimer radical cations such as $\text{Xe}_2^{\bullet+}$ can exchange, in a three-body collision, a Xe atom for a molecule M to form a $\text{XeM}^{\bullet+}$ radical cation. The latter can exchange, in a similar process, the second Xe atom for another molecule to form the dimer radical cation $\text{M}_2^{\bullet+}$. In this way, the water dimer radical cation $(\text{H}_2\text{O})_2^{\bullet+}$ has been generated. With this technique it is possible to measure thermochemical properties of such complexes. Thus, bracketing of the electron transfer processes $(\text{H}_2\text{O})_2^{\bullet+} + \text{M} \rightarrow \text{M}^{\bullet+} + \text{H}_2\text{O} + \text{H}_2\text{O}$ leads to an energy difference of 1030–1038 kJ mol^{-1} between $(\text{H}_2\text{O})_2^{\bullet+}$ and $\text{H}_2\text{O} + \text{H}_2\text{O}$. *Ab initio* calculations show that the H-bridged radical cation $\text{H}_2\text{O}-\text{H}^+\cdots\text{OH}^{\bullet}$ is 38 kJ mol^{-1} more stable than the ‘true’ ion–dipole complex $\text{H}_2\text{O}^{\bullet+}\cdots\text{OH}_2$ and that it lies 1021 kJ mol^{-1} below $\text{H}_2\text{O} + \text{H}_2\text{O}$, indicating that the observed species is in fact H-bridged.

Hydrogen-bridged radical cations, in particular $\text{O}\cdots\text{H}\cdots\text{O}$ bonded ions and their less stable $\text{C}\cdots\text{H}\cdots\text{O}$ bonded counterparts, are important intermediates in the dissociation chemistry of many oxygen-containing radical cations. They can interconvert via a so-called proton-transport catalysis. It was mentioned above that distonic radical cations are often more stable than their conventional counterparts and that they may be separated from those isomers by large barriers; see **Figure 4a** for the 1,2-H shift separating the conventional ion $\text{CH}_3\text{OH}^{\bullet+}$ and its distonic isomer $\text{CH}_2\text{OH}_2^{\bullet+}$. However, experiments and *ab initio* calculations show that interaction with an appropriately basic molecule, such as water or formaldehyde, greatly lowers the barrier. Thus the isomerization $\text{CH}_3\text{OH}^{\bullet+} \rightarrow \text{CH}_2\text{OH}_2^{\bullet+}$, which does not occur for the bare ions, is greatly accelerated by the addition of water; see **Figure 4b**. Here the water molecule attracts one of the methanol C-protons and then via a 5-membered ring donates one of its original protons to the O atom, thus producing $\text{CH}_2\text{OH}_2^{\bullet+}$. The barrier, which for the unassisted reaction is 108 kJ mol^{-1} , is

reduced to a mere 10 kJ mol^{-1} for the water-catalysed rearrangement. Proton transport catalysis has been shown to occur in many ionic rearrangement/dissociation processes. For example, the rearrangement $\text{CH}_2\text{OH}_2^{\bullet+} \rightarrow \text{CH}_3\text{OH}^{\bullet+}$, but now catalysed by formaldehyde, plays a key role in the low-energy rearrangement of ionized 1, 2-ethanediol. These are cases par excellence of effects induced by a single solvent molecule on the intrinsic chemistry of the ion.

Charge Transfer Complexes

Although charge (or electron) transfer complexes are not stable entities as such, *ab initio* calculations indicate that they do play a crucial role in the rearrangement of a variety of molecular ions. The situation often arises that a molecular ion $\text{M}-\text{DH}^{\bullet+}$ (D = dipole) rearranges to an ion–dipole complex of the type $\text{M}^{\bullet+} \rightarrow \text{D}-\text{H}$, where the arrow represents the dipole vector, and that a hydrogen needs to be transferred from the dipole molecule $\text{D}-\text{H}$ to $\text{M}^{\bullet+}$ in order to obtain the observed products $\text{MH}^+ + \text{D}^{\bullet}$. This, however, is not possible because in order to transfer its hydrogen to $\text{M}^{\bullet+}$, $\text{D}-\text{H}$ must rotate to such an extent that the resulting ion–dipole repulsion would lead to dissociation rather than to hydrogen transfer. In such cases charge (electron) transfer through orbital interaction ($\text{M}^{\bullet+} \rightarrow \text{D}-\text{H} \rightleftharpoons \text{M} \leftarrow \text{D}-\text{H}^{\bullet+}$) provides an alternative because now, and in contrast to the situation before charge transfer, the charged $\text{D}-\text{H}^{\bullet+}$ moiety is more or less free to rotate to produce $\text{M}\cdots\text{H}-\text{D}^{\bullet+}$ after which proton transfer takes place to produce $\text{MH}^+ + \text{D}^{\bullet}$. Thus, the charge transfer process kills two birds with one stone: it allows rotation of $\text{D}-\text{H}$ and subsequent proton transfer rather than hydrogen atom transfer.

Dications

Historically, dications were regarded as a curiosity and were observed only incidentally in mass spectrometric studies. Small polyatomic dications are remarkable species indeed; usually they are thermodynamically unstable with respect to dissociation into two monocations, but significantly kinetic stability may result if large barriers impede dissociation. This is illustrated by the methylenexonium dication $\text{CH}_2\text{OH}_2^{++}$ discussed above. This species is less stable than its dissociation products $\text{CH}_2\text{OH}^+ + \text{H}^+$ (by 105 kJ mol^{-1}), but a barrier of 250 kJ mol^{-1} makes the ion experimentally accessible, see **Figure 5**. In many cases, deprotonation of a dication is best viewed as a two-stage process. Initially, the departing unit is a hydrogen atom rather than a proton, and later an electron transfer takes place to form the products: $\text{AH}^{++} \rightarrow \text{A}^{++} - \text{H} \rightarrow \text{A}^+\cdots\text{H}^+ \rightarrow \text{A}^+ + \text{H}^+$. The first step, a homolytic cleavage, is responsible for the large barrier. Hence, a dication is truly a tiger in a cage.

Symbols

a_u	dimensionless trapping parameter ($u=r$ or z)
$\bar{D}_r$	depth of potential well in radial direction
$\bar{D}_z$	depth of potential well in axial direction
m	ion mass [amu]
n	order of frequency component
q_u	dimensionless trapping parameter ($u=r$ or z)
r_0	radius of ring electrode
u	collective coordinate axes r and z
U	DC potential
V	0-to-peak amplitude of the RF potential
z_0	half the separation of the end-cap electrodes, along the axis of cylindrical symmetry
β_z	trapping parameter $= (a_z + q_z^2/2)^{1/2}$
ξ	a dimensionless parameter $= \Omega t/2$
ω	fundamental frequency component
Ω	radial frequency of the applied RF potential

Introduction

An ion trap mass spectrometer functions both as a mass spectrometer of considerable mass range and variable mass resolution and as an ion store in which gaseous ions can be confined. Unlike other mass spectrometers that operate at pressures $<10^{-6}$ Torr, the ion trap operates at 1 mTorr of helium. As a storage device, the ion trap acts as an ‘electric-field test-tube’ for the confinement of gaseous ions either positively charged or negatively charged. The confining capacity of the ion trap arises from a trapping potential well formed when appropriate potentials are applied to the ion trap electrodes. The ion trap functions as a mass spectrometer when the trapping field is changed, so that the trajectories of simultaneously trapped ions of consecutive specific mass/charge ratio become sequentially unstable, and ions leave the trapping field in order of mass/charge ratio. Upon ejection from the ion trap, ions strike a detector and provide an output signal.

With the advent of new methods by which gaseous ions can be formed from polar molecules and injected into an ion trap, a wider range of ion trap applications is possible. The coupling of liquid chromatography (LC) with electrospray (ES) ionization and with mass

spectrometry (MS) in the early 1980s led to the development of new ion trap instruments for the analysis of nonvolatile, polar and thermally labile compounds. In 1995, new ion trap instruments (Finnigan’s LCQ and GCQ, and Bruker’s ESQUIRE) were introduced, which employ external ion sources with injection of ions into the ion trap. The major focus for the application of these instruments, using LC-ES/MS, is the examination of high-molecular-mass biopolymers such as proteins, peptides and oligodeoxyribonucleotides.

Several more ion trap devices have recently been developed but are outside the scope of this article, which only covers 3-D or Paul-type ion trap mass spectrometers. Linear ion trap derivatives of this technology were developed early this century. These devices offer advantages of higher ion capacity and sensitivity. The advent of orbital trapping techniques also took hold in this same time period, the resultant Orbitrap instruments offer resolution $>100\,000$ with a purely electrostatic type of mass spectrometer. While these devices are not treated in this article, suggested reading for them are provided at the end.

The Quadrupole Ion Trap Mass Spectrometer

The quadrupole ion trap consists of three electrodes which are shown in open array in **Figure 1**. Two of the electrodes are virtually identical and, while having hyperboloidal geometry, resemble small inverted saucers; these saucers are end-cap electrodes and are distinguishable by the number of holes in the centre of each electrode. One end-cap electrode has a single aperture through which electrons and/or ions can be gated, while the other has several apertures arranged centrally and through which ions pass to a detector. The third electrode, also of hyperboloidal geometry but of two sheets rather than one, is the ring electrode; it resembles a napkin holder and is of similar size, since the radius, r_0 , in the central plane is ~ 1 cm. The ring electrode is positioned symmetrically between two end-cap electrodes as shown in **Figure 2**; **Figure 2a** is a photograph of an ion trap cut in half along the axis of cylindrical symmetry, while **Figure 2b** is a cross section of an ideal ion trap showing the asymptotes and the dimensions r_0 and z_0 ,

Figure 1 The three electrodes of the quadrupole ion trap shown in open array.

where $2z_0$ is the separation of the end-cap electrodes along the axis of the ion trap.

The electrodes in **Figure 2** are truncated for practical purposes but, in theory, they extend to infinity and meet the asymptotes shown. The electrode geometries are defined so that, when an RF potential is applied to the ring electrode with the end-cap electrodes grounded, a near-ideal quadrupole field is produced, which creates a parabolic potential well for ion confinement, **Figure 3**. As shown in **Figure 3**, the potential well in the axial direction is of depth $\bar{D}_z$, while that in the radial direction $\bar{D}_r$; since $\bar{D}_z \approx 2\bar{D}_r$, the potential well resembles more a flower vase than a bowl.

Mass-selective ejection of ions from the potential well is accomplished by linearly ramping the amplitude of the RF potential; each ion species is ejected at a specific RF amplitude and, since the initial amplitude and ramping rate are known, the mass/charge ratio can be determined for each ion species. This method for measuring mass/charge ratios of confined ions was developed by Stafford and is known as the ‘mass-selective axial instability mode’; this method made possible the commercialization of the ion trap in the early 1980s. A prerequisite is that ions be focused initially to the ion trap centre by momentum-dissipating collisions with helium atoms.

History and Literature

The history of the quadrupole ion trap originates in the pioneering work of Paul and Steinwedel in the mid-1950s; their work was recognized by the award of the 1989 Nobel Prize in Physics to Wolfgang Paul. Yet the basis of the theory of operation of quadrupole devices was laid down over 140 years ago by Mathieu, from his investigation of vibrating stretched skins.

Figure 2 Quadrupole ion trap. (a) Photograph of an ion trap cut in half along the axis of cylindrical symmetry. (b) Schematic diagram of the three-dimensional ideal ion trap showing the asymptotes and the dimensions r_0 and z_0 .

Those papers that are landmarks in this field are listed in the bibliography together with the five texts in which are described a wide variety of applications of the ion trap. The history of this device has been expressed as several ‘ages’, beginning with mass-selective detection; this age, which covered the 1950s and began with disclosure of quadrupolar devices by Paul and Steinwedel,

Figure 3 Representation of the parabolic trapping potential wells of depths D_z and D_r .

included the storage of microparticles by Wuerker, Shelton and Langmuir and the first use of the ion trap as a mass spectrometer by Fischer. The second age is described as mass-selective storage and covers the period 1962–82. Detailed accounts of the development of the quadrupole-type devices during the early part of this period have been published by Dawson and Whetten and by Dawson; this latter publication has been reprinted in the series of ‘American Vacuum Society Classics’ by the American Institute of Physics under ISBN 1563964554. The third age (1983–88) is described as mass-selective ejection; this age ushered in the commercialization of the ion trap as a mass-selective detector for gas chromatograph and was a period of intense activity. In 1989, the present age of recent advances and developments commenced with the recognition of the work of Wolfgang Paul and Hans G. Dehmelt by the award, in part, of the Nobel Prize in Physics. In the same year, an account of the ion trap together with a full treatment of ion trap theory appeared in the text *Quadrupole Storage Mass Spectrometry* by March, Hughes and Todd; the historical account in this text by Todd was expanded into a full-scale review.

Other reviews have been contributed by Cooks and co-workers and a special collection reporting upon recent developments has also appeared. Ion trap mass spectrometry was reviewed for the 12th International Mass Spectrometry Conference in 1991. In 1995, three volumes entitled *Practical Aspects of Ion Trap Mass Spectrometry* were published in the CRC Series, Modern Mass Spectrometry. Volume 1 of this series, subtitled ‘Fundamentals of Ion Trap Mass Spectrometry’, covers the history of the ion trap, nonlinear ion traps, ion activation, ion–molecule reactions and ion trajectory simulations; the reader is referred to chapter 1 for a discussion of the Ages of the Quadrupole Ion Trap and to chapter 2 for an exposition of the mathematical basis of ion trap operation. Volume 2, subtitled ‘Ion Trap Instrumentation’, deals with enhancement of ion trap performance, confinement of externally generated ions, ion

structure differentiation, ion photodissociation, lasers and the ion trap, and ion traps in the study of Physics. Volume 3, subtitled ‘Chemical, Environmental and Bio-medical Applications’, includes a revisitation of fundamentals and expositions on gas chromatography–ion trap tandem mass spectrometry (GC–MS/MS) and liquid chromatography–ion trap tandem mass spectrometry (LC–MS/MS). More recently, an introduction to the quadrupole ion trap written in a tutorial form has been published. An excellent source of information is the publication entitled *Proceedings of the Annual Conference of the American Society for Mass Spectrometry and Allied Topics*.

The Trapping Potential Well

The trapping potential well created within the electrode assembly of an ion trap is of parabolic cross section; ion species are confined in layers in the well rather like an exotic drink of several liqueurs arranged carefully in horizontal layers according to their density, as shown in **Figure 4a**. However, the ions of lowest mass/charge ratio reside at the ion trap centre (bottom of the well) surrounded, like the centre of an onion, by layers of ions of increasing mass/charge ratio. Upon tilting the bowl to the right, equivalent to ramping the RF trapping potential, the layer of least density, corresponding to ions of highest mass/charge ratio, will be poured from the well. To withdraw the layer of greatest density, that is, ions of lowest mass/charge ratio, a ‘straw’ is introduced and the bottom layer is sucked out as shown in **Figure 4b**; the straw represents axial modulation (see below) and the liqueur glass in **Figure 4b** corresponds to the detector.

For an ideal quadrupole field, the following identity is given,

$$r_0^2 = 2z_0^2 \quad [1]$$

so that once the magnitude of r_0 is given the sizes of all three electrodes and the electrode spacings are fixed; in the majority of commercial ion traps, r_0 lies in the range 0.7–1.0 cm.

The Theory of Ion Trap Operation

The motions of ions in quadrupole devices differ markedly from those in magnetic and electrostatic sectors. The quadrupole ion trap is described as a *dynamic* instrument since ion trajectories are influenced by time-dependent forces.

An Ion in a Quadrupole Field

An ion in a quadrupole field experiences strong focusing in that the restoring force, which drives the ion back

Figure 4 (a) Schematic presentation of a trapping parabolic potential well where the three liquids differing in density represent ions differing in mass/charge ratio. (b) The tilting of the well corresponds to ramping of the RF potential while the straw, with which ions are withdrawn in order of increasing mass/charge ratio, represents axial modulation.

towards the centre of the device, increases as the ion deviates from the centre. The resulting ion trajectories resemble Lissajous figures (figures-of-eight) and the motion of ions is described mathematically by the solutions to the second-order linear differential equation described originally by Mathieu from his investigation of the mathematics of vibrating stretched skins. He described solutions in terms of regions of stability and instability; these solutions and the criteria for stability and instability also describe the trajectories of ions confined in quadrupole devices and define the limits to trajectory stability.

The Mathieu Equation

The canonical form of the Mathieu equation is

$$\frac{d^2 u}{d\xi^2} + (a_u - 2q_u \cos 2\xi)u = 0 \quad [2]$$

where u represents the coordinate axes r and z , ξ is a dimensionless parameter equal to $\Omega t/2$, Ω (for the ion trap) is the radial frequency of the RF potential applied to the ring and a_u and q_u are dimensionless trapping parameters. For the quadrupole ion trap, the trapping parameters are expressed as

$$a_r = \frac{4eU}{mr_0^2\Omega^2}; \quad q_r = \frac{-2eV}{mr_0^2\Omega^2} \quad [3]$$

$$a_z = \frac{-8eU}{mr_0^2\Omega^2}; \quad q_z = \frac{4eV}{mr_0^2\Omega^2} \quad [4]$$

where U is a DC potential and V is the amplitude of the RF potential of the form $V\cos \Omega t$. It is seen that $a_z = -2a_r$ and $q_z = -2q_r$.

Since $U = 0$, a_r and a_z are equal to zero and the common mode of ion trap operation corresponds to operation on the q_z axis of the stability diagram. The expression for q_z contains the mass/charge ratio for a given ion, the size of the ion trap, r_0 , the amplitude V of the RF potential and the radial frequency Ω that is, all of the parameters that are needed to understand the operations of the ion trap.

The ‘Stretched’ Ion Trap

The ion trap electrodes are truncated in order to obtain a practical instrument, but this truncation introduces higher-order multipole components to the potential. To compensate for these multipole components, the electrodes of commercial devices prior to 1995 were assembled with a ‘stretched’ separation of the end-cap electrodes; the value of z_0 was increased by 10.6%. An account of the ‘stretching’ of the ion trap is given by Syka in chapter 4 of volume 1 in the CRC books, while in chapter 3 is presented an account by Franzen, Gabling, Schubert and Wang of nonlinear ion traps. The immediate consequences of stretching are that the asymptotes to the end-cap electrodes no longer coincide with those for the ring electrode, $r_0^2 \neq 2z_0^2$ and the values of the trapping parameters are changed. The trapping parameters are now expressed as

$$a_r = \frac{8eU}{m(r_0^2 + 2z_0^2)\Omega^2}; \quad q_r = \frac{-4eV}{m(r_0^2 + 2z_0^2)\Omega^2} \quad [5]$$

and

$$a_z = \frac{-16eU}{m(r_0^2 + 2z_0^2)\Omega^2}; \quad q_z = \frac{8eV}{m(r_0^2 + 2z_0^2)\Omega^2} \quad [6]$$

For the ion trap in the LCQ and GCQ instruments, $r_0 = 0.707$ cm and $z_0 = 0.785$ cm, such that the geometry has been stretched by $\sim 57\%$.

Regions of Ion Trajectory Stability

Quadrupole ion trap operation is concerned with the criteria that govern the stability of an ion trajectory in both r and z directions within the field, that is, the experimental conditions that determine whether or not an ion is stored.

The solutions to Mathieu's equation are of two types, (i) periodic but unstable, and (ii) periodic and stable. Solutions of type (i) form the boundaries of unstable regions on the stability diagram and correspond to those values of a trapping parameter β_z that are integers, that is, 0, 1, 2, 3, ...; β_z is a complex function of a_z and q_z that is approximated as

$$\beta_z = \sqrt{a_z + \frac{q_z^2}{2}} \quad [7]$$

for $q_z < 0.4$. The boundaries represent, in practical terms, the point at which an ion trajectory becomes unbounded. Solutions of type (ii) determine ion motion in an ion trap. The stability regions corresponding to stable solutions in the z -direction are shaded and labelled z -stable in **Figure 5a**, while those corresponding to stable solutions in the r -direction are shaded and labelled r -stable in **Figure 5b**; the latter are doubled in magnitude along the ordinate and inverted.

Ions are confined in the ion trap provided their trajectories are stable in the r and z directions simultaneously; such trajectory stability is obtained in the region closest to the origin, that is, region A in **Figure 6**, which is plotted in a_u, q_u space, that is, where a_u is plotted against q_u . Regions A and B are referred to as stability regions; region A is shown in detail in **Figure 7**. The coordinates of the stability region in **Figure 7** are the parameters a_z and q_z . In **Figure 7**, the $\beta_z = 1$ stability boundary intersects with the q_z axis at $q_z = 0.908$; this intersection is the working point of the ion of lowest mass/charge ratio that can be stored.

Secular Frequencies

A three-dimensional representation of an ion trajectory, shown in **Figure 8**, has the general appearance of a Lissajous curve composed of two fundamental frequency components, ω_{r0} and ω_{z0} , of the secular motion. Higher-order

Figure 5 Several Mathieu stability regions for the three-dimensional quadrupole field. (a) Diagrams for the z direction of (a_z, q_z) space. (b) Diagrams for the r direction of (a_z, q_z) space.

Figure 6 The Mathieu stability diagram in (a_z, q_z) space for the quadrupole ion trap in both the r and z directions. Regions of simultaneous overlap are labelled A and B.

(n) frequencies exist and the family of frequencies is described by $\omega_{r,n}$ and $\omega_{z,n}$ as given by

$$\omega_{u,n} = (n + \beta_u/2)\Omega; \quad 0 \leq n < \infty \quad [8]$$

and

$$\omega_{u,n} = -(n + \beta_u/2)\Omega; \quad -\infty < n < 0 \quad [9]$$

Figure 7 Stability diagram in (a_z, q_z) space for the region of simultaneous stability in both r and z directions near the origin for the three-dimensional quadrupole ion trap; the iso- β_r and iso- β_z lines are shown. The q_z axis intersects the $\beta_z=1$ boundary at $q_z=0.908$, which corresponds to $q_{\max}$ in the mass-selective instability mode.

Figure 8 Trajectory of a trapped ion of m/z 105. The initial position was selected randomly from a population with an initial gaussian distribution (FWHM of 1 mm); $q_z = 0.3$; zero initial velocity. The projection onto the xy plane illustrates planar motion in three-dimensional space. The trajectory develops a shape that resembles a flattened boomerang. Reproduced from Nappi et al. (1997) *International Journal of Mass Spectrometry and Ion Processes* 161 : 77–85.

The simulated ion trajectory shown in **Figure 8** resembles a roller-coaster ride and depicts the motion of an ion on the potential shown in **Figure 9**. The oscillatory motion of the ion results from the undulations of the potential surface, which can be envisaged as rotating. The simulation of the ion trajectory was carried out using

Figure 9 Pure quadrupole field, or potential surface, for a quadrupole ion trap. Note the four poles of the surface and the similarity of the field shape to the trajectory in **Figure 8**.

the ITSIM simulation program, while the potential surface was generated by calculating the potential for increments of 1 mm in both radial and axial directions.

Resonant Excitation

The motion of confined ions can be excited upon resonant irradiation at ω_z ; resonant excitation is a powerful technique in ion trap mass spectrometry since predetermined waveforms composed of specified frequencies or frequency ranges can be used. Irradiation is effected by applying a supplementary potential of some hundreds of millivolts across the end-cap electrodes. Prior to resonant excitation, ions are focused collisionally to the ion trap centre by collisions with helium atoms. This process is described as 'ion cooling' in that ion kinetic energies are reduced to ~ 0.1 eV, corresponding to ~ 800 K. Resonant excitation, or 'tickling' of cooled ions, causes ions to move away from the ion trap centre so that they experience the trapping field and are accelerated to kinetic energies of tens of electronvolts.

Resonant excitation is used to increase ion kinetic energy for the following purposes. (1) To eject unwanted ions during ionization and to isolate a narrow range of mass/charge ratios. (2) To promote endothermic ion/molecule reactions. (3) To increase ion internal energy through momentum-exchange collisions with helium atoms; in the limit, ions dissociate. (4) To move ions towards an end-cap electrode where an image current can be detected for their nondestructive measurement and re-measurement. (5) To eject ions either for ion isolation or for mass-selective ejection while the applied frequency is swept. (6) To eject ions while the amplitude V of the main RF potential is ramped up; this mode, known as axial modulation, uses a fixed frequency to

eject ions just before their trajectories become unstable. In axial modulation, the resonant frequency is slightly less than half the main drive frequency Ω . Resonant excitation at lower frequencies has been used with great success to extend the normal mass range of the ion trap.

Operation of the Ion Trap as a Mass Spectrometer

In the ion trap, gaseous molecules are bombarded with 50–80 eV electrons emitted from a heated filament and gated into the trap, as shown in **Figure 10a**. Under automatic gain control (AGC), the number of ions formed during 200- μ s is used to scale the ionization time and produce the required number of ions. During ionization, an RF voltage V_0 is applied to the ring electrode so as to confine ions in a given range of mass/charge ratio. Nascent ions are subjected to about 20 collisions per millisecond with helium at a pressure of 10^{-3} torr; those ions that are not ejected become focused near the trap centre. In **Figure 10b**, an RF amplitude is ramped over the period 30–85 ms, during which mass-selective ion ejection and mass analysis occur.

Each ion species confined within the ion trap is associated with a q_z value that lies on the q_z axis on the stability diagram; ions of high mass/charge ratio have q_z values near the origin, while ions of lower mass/charge ratio have q_z values that extend towards the $\beta_z = 1$ stability boundary, as shown diagrammatically using stick-people of various sizes in **Figure 11a**. At the intersection of the $\beta_z = 1$ stability boundary and the q_z axis, where $q_z = 0.908$ (see **Figure 7**), the trajectories of trapped ions become unstable axially and ions leave the ion trap. Once the ion cloud has been focused collisionally to the ion trap centre, the amplitude of the RF potential is ramped; this operation, which is described as an analytical ramp

Figure 10 An overview of MS-in-time. (a) Step 1: a trapping RF amplitude is applied for 0–30 ms during which ions are formed from sample molecules and stored. (b) Step 2: an RF amplitude is ramped over the period 30–85 ms during which mass-selective ion ejection and mass analysis occurs.

or analytical scan, increases the q_z values of all ion species and, when $q_z = 0.908$ for each ion species, the ions are ejected axially through the end-cap electrodes. This mass-selective axial instability method of ion ejection has been supplanted by the use of axial modulation. Originally, axial modulation described resonant ejection of ions at a frequency of 485 kHz and at a q_z value slightly less than 0.908. When the RF amplitude is ramped, ions come into resonance at 485 kHz as their q_z values approach 0.908 and are ejected axially in order of increasing mass/charge ratio. Since ions are focused near the ion trap centre in the fashion of an onion, resonance ejection has the effect of removing the ions of low mass/charge ratio residing in the innermost layer of the onion from the influence of space-charge perturbations induced by other ion species, so that ions are ejected free of space-charge and with enhanced mass resolution. Resonant ejection, which can be carried out over a wide frequency range, is depicted pictorially in **Figure 11b**, which shows ions residing near the bottom of their respective axial

Figure 11 (a) Schematic representation of working points (that is, coordinates in a_z, q_z space) in the stability diagram for several species of ions stored concurrently. The arrangement of working points with respect to mass/charge ratio is depicted by figures that differ in size. (b) Ions are shown residing near the bottom of their respective axial potential wells of depth $\bar{D}_z$; the ladder represents the opportunity for resonant ejection of an ion species.

potential wells of depth $\bar{D}_z$; the ladder represents resonant ejection of an ion species. For axial modulation, the ladder is positioned at a q_z value slightly less than 0.908. Resonantly ejected ions pass through holes in both end-cap electrodes so that $\sim 50\%$ impinge upon an electron multiplier located behind one of the end-cap electrodes; ion signals are created that produce a mass spectrum in order of increasing mass/charge ratio.

A mass spectrum is obtained by running the scan function (see below) a number of times specified by the number of microscans; the signals from each microscan are averaged and yield a mass spectrum.

Scan Function

The above operation can be expressed succinctly in a scan function, which shows the temporal variation of the potentials applied to the electrodes such that a scan function is a visual representation of the sequence of program segments in the software that controls ion trap operation. The scan function for the above mass spectrometric operation is shown in Figure 12.

Collision-Induced Dissociation

Collision-induced dissociation (CID) of an isolated ion species in a quadrupole ion trap is a powerful technique for both the determination of ion structures and the analytical identification of compounds with high

Figure 12 Scan function for obtaining an EI mass spectrum. The scan function shows the ionization period, A, followed immediately by the analytical ramp with concurrent axial modulation. Note that the pre-scan for the automatic gain control algorithm is not shown.

specificity. Under the influence of the tickle voltage, ions are moved from the centre to a region of higher potential, whereupon they are accelerated and their kinetic energies are increased. Subsequent collisions with helium atoms lead to enhancement of ion internal energy. In analytical applications, where the objective is to dissociate all isolated ions and to maximize the trapping of fragment ions produced, ion kinetic energy uptake must be balanced with incremental accumulation of internal energy so that ejection of isolated ions and fragment ions is avoided.

Tandem Mass Spectrometry

Tandem (Latin: “at length”) mass spectrometry, MS/MS, is the practice of performing one mass-selective operation after another, much as the riders are seated on a tandem bicycle. The first mass-selective operation isolates an ion species designated as the parent ion, while the second determines the mass/charge ratios of the fragment, or product, ions formed by CID of the parent ions. MS/MS with a quadrupole ion trap, where successive mass-selective operations are carried out in time, offers a number of advantages. First, since the ion trap operates in a pulsed mode, mass-selected ions can be accumulated over time. Second, since CID is wrought by many collisions of mass-selected ions with helium atoms wherein the energy transferred per collision is small, dissociation channels of lowest activation energy are accessed almost exclusively. Third, all isolated ions can be dissociated and fragment ions arising from some 90% of them can be confined. Fourth, a sequence of several mass-selective operations can be performed as in MS n .

When gas chromatography is interfaced with an ion trap tandem mass spectrometer, individual compounds can be detected at the hundreds of femtograms level. The high specificity or informing power obtainable with GC-MS/MS is achieved by observation of specific fragment ion signals from an isolated molecular ion species M^{*+} formed from M that elutes within a specified retention-time window.

Chemical Ionization and Ion Molecule Reactions

In the quadrupole ion trap, several types of reactions can and do occur simultaneously and spontaneously once electron ionization of a compound has occurred. Ion-molecule reactions involving charge transfer, proton transfer and clustering occur sequentially, resulting in the formation of stable even-electron ions. Proton transfer chemical ionization (CI) involves the transfer to a neutral species of a proton (or other even-electron charged particles) from an ion that has been formed in an

ion–molecule reaction. Common CI reagents are CH_5^+ and C_2H_5^+ , which are formed rapidly and can be isolated prior to reaction. CI reagent ions can be created externally and injected into the ion trap, isolated mass-selectively and allowed to react with sample molecules.

Conclusions

Ion trap mass spectrometry is a versatile technique of high sensitivity and high specificity. The relatively low cost of commercial instrumentation has permitted a substantial growth in the practice of mass spectrometry. The theory of ion trap operation differs from those of other mass spectrometers and presents an exciting challenge to the mass spectrometry community.

IR and Raman Spectroscopy of Inorganic, Coordination and Organometallic Compounds

Infrared (IR) and Raman spectroscopy techniques are employed for the recognition and the quantitative analysis of structural units in unknown compounds. The IR region of the electromagnetic spectrum extends from the red end of the visible spectrum to the microwave region. It includes radiation at wavelengths between 14 000 and 20 cm^{-1} , but the spectral range used most is the mid-IR, which covers frequencies from 4000 to 200 cm^{-1} . IR spectroscopy involves examination of the twisting, bending, rotating and vibrational motions of atoms in a molecule. On interaction with IR radiation, portions of the incident radiation are absorbed at specific wavelengths. The multiplicity of vibrations occurring simultaneously produces a highly complex absorption spectrum that is uniquely characteristic of the functional groups that make up the molecule and of the overall configuration of the molecule as well.

When monochromatic radiation is scattered by molecules, a small fraction of the scattered radiation is observed to have a different frequency from that of the incident radiation; this is known as the *Raman effect*. Since its discovery in 1928, the Raman effect has been an important method for the elucidation of molecular structure, for locating various functional groups or chemical bonds in molecules and for the quantitative analysis of complex mixtures. Although vibrational Raman spectra are related to IR absorption spectra, a Raman spectrum arises in a different manner and thus often provides complementary information. Vibrations that are active in Raman scattering may be inactive in IR, and vice versa. A unique feature of Raman scattering is that each line has a characteristic polarization, and polarization data provide additional information about molecular structure.

Raman spectra can be used to study materials in aqueous solutions, a medium that transmits IR radiation very poorly. Another advantage is the ability to examine the entire vibrational spectrum with one instrument, unlike IR spectroscopy in which the far-IR is usually scanned separately from the mid-IR. For quantitative determinations, the Raman scattering power is directly proportional to concentration, whereas, in IR spectroscopy, it is the logarithm of the ratio of incident to transmitted power, the absorbance, that is proportional to concentration. Furthermore, the application of IR spectroscopy to the identification of

inorganic and coordination compounds has been somewhat unsuccessful because many simple inorganic compounds such as the borides, nitrides and oxides do not exhibit absorption in the region between 4000 and 600 cm^{-1} , which for many years was the range of the IR region covered by most commercially available spectrometers.

In addition, the Raman technique has proved to be particularly valuable in the study of single crystals where the IR technique has greater limitations on sample size and geometry. Polarization data obtained from Raman spectra allow unambiguous classification of fundamentals and lattice modes into the various symmetry classes. Although Raman spectroscopy will never challenge X-ray diffraction as a tool for quantitative structural analysis, it is the preferred technique when qualitative information is sufficient because it is faster and less expensive.

Experimental Aspects

The spectrum obtained for a given sample of inorganic, coordination or organometallic compounds depends on the physical state of the sample. Gaseous samples usually exhibit a rotational fine structure which is damped in solution because collisions of molecules in the condensed phase occur before a rotation is completed. In addition to the difference in resolved fine structure, the number of absorption bands and the frequencies of the vibrations vary in the different states. Often there are more bands in the liquid state than in the gaseous state of a substance, and frequently new bands below 300 cm^{-1} caused by *lattice vibrations*, i.e., translational and torsional motions of the molecules in the lattice (*phonon modes*) appear in the solid-state spectrum. The stronger intermolecular forces that exist in the solid and liquid states compared with those in the gaseous state are often the cause of slight shifts in the frequencies.

An additional complication arises if the unit cell of the crystal contains more than one chemically equivalent molecule. When this is the case, the vibrations in the individual molecules can couple with each other. This intermolecular coupling can give rise to frequency shifts and band splitting.

Sample handling also presents a number of problems in the IR region. For example, there is no rugged window

material for cuvettes that is transparent and also inert over this region. The alkali halides are widely used, particularly sodium chloride, which is transparent at wavelengths as long as 625 cm^{-1} . For frequencies less than 600 cm^{-1} , polyethylene cells are frequently used.

Samples that are liquid at room temperature are usually scanned in their neat form or in solution. Unfortunately, not all substances are soluble to a reasonable concentration in a solvent clear of absorption in the regions of interest. In some cases use is made of solvents susceptible to hydrogen-bonding effects which can alter the vibrational frequency characteristic of the compound examined; the stronger the hydrogen bonding, the more the fundamental frequency is lowered.

Powders or solids can be examined as a thin paste or mull (mineral oil, nujol, hexachlorobutadiene, perfluorokerosene) or through the pellet technique which allows quantitative analyses to be performed since accurate measurements can be made of the ratio of weight of sample to internal standard in each disk. A more modern technique using diamond ATR is removing the need for mulls and disks.

The use of laser excitation allows Raman spectroscopy to be performed on specimens in almost any state: liquid, solution, transparent solid, translucent solid, powder, pellet or gas. Water is a weak scatterer and therefore an excellent solvent for Raman work. This has important consequences in studies of biochemical interest and in the pharmaceutical industry. Water is a bad solvent in FT Raman because the Raman light is self-absorbed.

Group Frequencies and Band Assignments

The IR spectrum of a compound is essentially the superposition of absorption bands of specific functional groups: even small interactions with the surrounding atoms of the molecule impose the stamp of individuality on the spectrum of each compound. For qualitative analysis, one of the best features of an IR spectrum is that the absorption or the *lack of absorption* in specific frequency regions can be correlated with specific stretching and bending motions and, in some cases, with the relationship of these groups to the rest of the molecule.

In the near-IR region (NIR), which meets the visible region at approximately $12\,500\text{ cm}^{-1}$ and extends to approximately 4000 cm^{-1} , generally there are many absorption bands that result from harmonic overtones of fundamental and combination bands often associated with hydrogen atoms.

Many useful correlations have been found in the mid-IR region. This region is divided into the 'group frequency' region, $4000\text{--}1300\text{ cm}^{-1}$, and the fingerprint region, $1300\text{--}650\text{ cm}^{-1}$. In the group frequency region,

the principal absorption bands are assigned to vibration units consisting of only two atoms of a molecule; in the interval from 4000 to 2500 cm^{-1} , the absorption is characteristic of hydrogen stretching vibrations with elements of mass 19 or less. The intermediate frequency range, $2500\text{--}1540\text{ cm}^{-1}$ (*unsaturated* region), contains triple-bond frequencies which appear from 2500 to 2000 cm^{-1} and double-bond frequencies from 2000 to 1540 cm^{-1} . In the region between 1300 and 650 cm^{-1} , there are single bond stretching frequencies and bending vibrations (skeletal frequencies) of polyatomic systems that involve motions of bonds linking a substituent group to the remainder of the molecule.

The region $667\text{--}10\text{ cm}^{-1}$ contains the bending vibrations of carbon, nitrogen, oxygen and fluorine with atoms heavier than mass 19, and additional bending motions in cyclic or unsaturated systems. The low-frequency molecular vibrations in the far-IR are particularly sensitive to changes in the overall structure of the molecule; thus, the far-IR bands often differ in a predictable manner for different isomeric forms of compound.

The far-IR frequencies of organometallic compounds are often sensitive to the metal ion or atom, and this can be used advantageously in the study of coordination bonds. Moreover, this region is particularly well suited to the study of organometallic or inorganic compounds whose atoms are heavy and whose bonds are inclined to be weak.

In Raman spectroscopy, those vibrations that originate in relatively nonpolar bonds with symmetrical charge distributions and that are symmetrical in nature produce the greatest polarizability changes and are the most intense. Vibrations from --C=C-- , $\text{--C}\equiv\text{C--}$, $\text{--C}\equiv\text{N--}$, --C=S-- , --C--S-- , --S--S-- , --N=N-- and --S--H bonds are readily observed. Absorption bands due to the skeletal vibrations of finite chains and rings of saturated and unsaturated hydrocarbons are generally sharper in Raman than in IR spectra. Aromatic compounds exhibit particularly strong spectra with a strong ring deformation mode at $1600 \pm 30\text{ cm}^{-1}$. Skeletal motions are very characteristic and highly useful for cyclic and aromatic rings, steroids and long chains of methylene groups.

In solid samples, sharpening and intensifying of certain bands appear to be a function of crystallinity. For all molecules that have a centre of symmetry, a band allowed in the IR is forbidden in the Raman, and vice versa. In molecules with symmetry elements other than a centre of symmetry, certain bands may be active in the Raman, IR, both or neither. For a complex molecule that has no symmetry, all of the normal vibrational modes are allowed in both the IR and Raman spectra. One other strong difference is the tendency for peaks in a Raman spectrum to have a greater range of intensities, from very weak to very strong. These factors, plus the contrasting relative intensities for a given group, are the main basis for making more confident assignment of chemical structure through the combination of

IR and Raman data. For example, in IR spectra, the 3300 cm^{-1} region is badly obscured by intense OH absorption, whereas the same region in Raman is very helpful in the assignment of NH and CH stretchings because the OH absorption is weak.

Applications

Selection Rules

Molecular symmetry is very important in determining the IR activity and degeneracy of a molecular vibration. When a molecule is present in a crystal, the symmetry of the surroundings of the molecule in the unit cell, the so-called *site symmetry*, determines the selection rules. Often, bands forbidden in the gaseous state or in solution appear in the solid, and degenerate vibrations in the gaseous state are split in the solid. To show this effect, consider the IR spectra of carbonate derivatives. The IR (Figure 1(a)) and Raman spectra of CaCO_3 in calcite, where the carbonate ion is in a site of D_3 symmetry, contain the following bands (in cm^{-1}): ν_1 , 1087 (R); ν_2 , 879 (IR); ν_3 , 11432 (IR, R); ν_4 , 710 (IR, R). The IR spectra of CaCO_3 (Figure 1(b)) in aragonite, where the site symmetry for the carbonate is C_8 is different: ν_1 is IR active and both ν_3 and ν_4 split into two bands.

In Figure 2 some of the possible structures for a compound with an empirical formula NSF_3 are shown whereas the calculated number and symmetry of bands for the illustrated structures are listed in Table 1. In the IR spectrum of this compound, six intense bands are found, in agreement with a C_{3v} structure but certainly not in conflict with other possible structures. It was found that the four bands ν_1 , ν_2 , ν_3 and ν_5 have *P*, *Q* and *R* branches indicating that the molecule investigated is a symmetric top molecule and supports a C_{3v} structure. The spectral data are contained in Table 2.

Figure 1 IR spectra of CaCO_3 in calcite and in aragonite.

These data, combined with an NMR study, have been employed to support the C_{3v} structure F_3SN . The F_3SN structure has not been eliminated by these data; however, the other observed bands support F_3SN : the S–N stretch is the only fundamental vibration that could be expected at a frequency of 1515 cm^{-1} . The NF stretching vibrations in NF_3 occur at 1031 cm^{-1} and would not be expected to be as high as 1515 cm^{-1} in F_3NS . The F_3SN structure has also been demonstrated on the basis of microwave and mass spectroscopic studies.

Change in the Spectra of Donor Molecules on Coordination

In the IR spectrum of *N,N*-dimethylacetamide in CCl_4 , a strong absorption band at 1662 cm^{-1} has been found due to a highly coupled carbonyl absorption. The low frequency with respect to that found for acetone (1715 cm^{-1})

Figure 3 Resonance interaction between the carbonyl and the lone pair on the nitrogen in *N,N'*-dimethylacetamide.

is attributed to a resonance interaction with the lone pair on the nitrogen (**Figure 3**).

A decrease in the frequency of this band has generally been found on complexation of the molecule with Lewis acids. This has been attributed to coordination of the oxygen to the acid. Oxygen coordination produces a decrease in the carbonyl force constant by draining the π electron density out of the carbonyl group, which causes the observed decrease in the carbonyl frequency. The absence of any absorption in the carbonyl region on the high-frequency side of the uncomplexed carbonyl band further supports coordination of this molecule through the oxygen. However, in $\text{Pd}(\text{NH}_2\text{CONH}_2)_2\text{Cl}_2$, and $\text{Pt}(\text{NH}_2\text{CONH}_2)_2\text{Cl}_2$, coordination of the ligand NH_2CONH_2 through the nitrogen occurs, which results in a decrease in the C–N vibration frequency and in a higher frequency carbonyl absorption.

Analogously, a decrease in the S–O stretching frequency, indicative of oxygen coordination, is observed when dimethyl sulfoxide or tetramethylene sulfoxide is complexed to many metal ions, iodine and phenol, whereas the S–O stretching frequency increases in the palladium complex of dimethyl sulfoxide, compared to free sulfoxide, which suggests sulphur coordination.

The IR spectra of ethylenediaminetetraacetic acid metal complexes have been used to distinguish between tetradentate, pentadentate or hexadentate coordination of the ligand on the basis of the absorption bands in the carbonyl region corresponding to free and complexed carbonyl groups.

The change in $\text{C}\equiv\text{N}$ stretching frequency of nitriles and metal cyanides resulting from their interaction with Lewis acids has also attracted considerable interest. When such molecules are coordinated to Lewis acids not generally involved in π back-bonding, the $\text{C}\equiv\text{N}$ stretching frequency increases. A combined molecular orbital and normal coordinate analysis of acetonitrile and some of its adducts indicate that a slight increase is to be expected from this effect, but that the principal contribution to the observed shift arises from an increase in the $\text{C}\equiv\text{N}$ force constant. This increase is mainly due to an increase in the $\text{C}\equiv\text{N}$ σ -bond strength from nitrogen rehybridization. In those systems where there is extensive π back-bonding from the acid into the π^* orbitals of the nitrile group, the decreased π bond energy accounts for the decreased frequency.

Change in Symmetry on Coordination

Some of the most useful applications of IR spectroscopy in the area of coordination and organometallic chemistry originate from the change in the symmetry of a ligand on coordination. For example, when small molecules (e.g. N_2 , O_2 and H_2) are linked to transition metal ions a symmetry change occurs which has a strong influence on the IR spectra. The stretching vibration of free N_2 is IR inactive but Raman active (2331 cm^{-1}). If the azide ion is added to $\text{Ru}(\text{NH}_3)_5\text{H}_2\text{O}^{3+}$, $\text{Ru}(\text{NH}_3)_5\text{N}_2^{2+}$ is obtained, which exhibits in IR a sharp absorption due to $\nu(\text{N}-\text{N})$ at 2130 cm^{-1} .

IR spectroscopy is a very effective tool for determining the nature of the bonding of the sulfate group in its derivatives. The sulfate ion (T_d symmetry) has two IR bands in the $1200\text{--}600\text{ cm}^{-1}$ region, one assigned to ν_3 at 1104 cm^{-1} and one to ν_4 at 613 cm^{-1} . In the complex $[\text{Co}(\text{NH}_3)_5\text{OSO}_3]\text{Br}$ the coordinated group has lower symmetry, C_{3v} , with six new bands at 970 (ν_1), 438 (ν_2), 1032 to 1044 and 1117 to 1143 (from ν_3), and 645 and 604 cm^{-1} (from ν_4). In a bridged group, the symmetry is lowered to C_{2v} and even more bands appear: the ν_3 band is split into three peaks and the ν_4 band into three other peaks.

Five-coordinate addition compounds such as $(\text{CH}_3)_3\text{SnCl}\cdot(\text{CH}_3)_2\text{SO}$ have a structure in which the three methyl groups are in the equatorial positions: in fact, the symmetric Sn–C stretch present in $(\text{CH}_3)_3\text{SnCl}$ at 545 cm^{-1} disappears in the addition compound where a single Sn–C vibration due to the asymmetric Sn–C stretch is detected at 551 cm^{-1} . This is in accordance with an isomer with three methyl groups in the equatorial position: in fact, a small dipole moment change is associated with the symmetric stretch in compounds having this structure. All the other possible structures possess at least two different Sn–C vibrations.

Also, the carbonyl stretching vibrations of $\text{M}(\text{CO})_5\text{X}$ (and their ^{13}C -substituted) derivatives can be employed to study change in symmetry on coordination. The operations or the C_{4v} point group for all- ^{12}CO compounds such as those in **Figure 4** produce $2A_1$ (one radial and one axial), B_1 (radial) and E (radial) vibrations, three of which are IR active and four Raman active.

If the molecule has an axial ^{13}CO , the symmetry is still C_{4v} and the B_1 and E modes (which have no contribution from the axial group) will be unaffected by the mass change. The two A_1 modes having the same symmetry will mix, so isotopic substitution could affect both, but it will have a major effect on A_1 (axial). If a ^{13}CO is located in the radial position, the symmetry is lowered to C_s , leading to the possible vibrations shown in **Figure 5**.

Only the A'' vibration will be unaffected by the mass change, and it resembles the E mode in the all- ^{12}CO

Figure 4 Carbonyl stretching vibrations of $M(^{12}\text{CO})_5\text{X}$ derivatives.

Figure 5 Possible vibrations for a $M(^{12}\text{CO})_4(^{13}\text{CO})\text{X}$ derivative, containing the ^{13}CO in the radial position.

molecule. All of the other four modes can mix and could be shifted by distributing the mass effect over all four modes. This would shift the vibrations to lower frequencies than those in the all- ^{12}CO molecule. Several normal coordinate analyses on such systems, employing a large number of isotopes, have been made which indicates that as the formal positive charge on the central atom increases in forming $M(\text{CO})_5\text{Br}$ from $M(\text{CO})_6$, the σ -bonding increases and the extent of π back-bonding decreases.

Metal-Isotope Spectroscopy

The metal–ligand vibrations appear in the low-frequency region ($600\text{--}100\text{ cm}^{-1}$) and provide direct information about the structure of the coordination sphere and the nature of the metal–ligand bond. It is difficult to make unequivocal assignments of metal–ligand vibrations since the interpretation of the low-frequency spectrum is complicated by the appearance of ligand vibrations, as well as lattice vibrations in the case of solid-state spectra. However, different methods can be employed: for example, the metal–ligand vibrations are absent in the spectrum of the free donor (it should be taken into account that in some cases new ligand vibrations, activated by complex formation, can appear).

Metal–ligand vibrations are also metal sensitive and are shifted by changing the metal or its oxidation state: this method is applicable only to isostructural metal complexes, and it does not provide definitive assignments since some ligand vibrations (e.g. the chelate ring deformations) are also metal sensitive.

If the ligand is isotopically substituted, the metal–ligand vibrations present an isotope shift: the $\nu(\text{Ni–N})$ in $[\text{Ni}(\text{NH}_3)_6]\text{Cl}_2$ at 334 cm^{-1} is shifted to 318 cm^{-1} on deuteration of the ammonia groups. It is possible, with this method, to assign the metal–ligand vibrations of chelate compounds such as oxamido ($^{14}\text{N}/^{15}\text{N}$) and acetylacetonato ($^{16}\text{O}/^{17}\text{O}$) complexes. However, isotopic substitution of the α -atom (an atom directly bonded to the metal) causes shifts not only of metal–ligand vibrations but also of ligand vibrations involving the motion of the α -atom. Finally, the frequency of a metal–ligand vibration may also be predicted if the metal–ligand stretching and other force constants are known a priori.

The ‘metal-isotope technique’ is the best one for obtaining reliable metal–ligand assignments. Isotope pairs such as (H/D) and ($^{16}\text{O}/^{17}\text{O}$) had been used in the past routinely by many spectroscopists. Isotopic pairs of heavy metals such as ($^{58}\text{Ni}/^{62}\text{Ni}$) and ($^{104}\text{Pd}/^{110}\text{Pd}$) were not employed until 1969 when the first report on the assignments of the Ni–P vibrations of *trans*- $\text{Ni}(\text{PEt}_3)_2\text{X}_2$ (X = Cl and Br) was made. The delay in their use was probably due to the high cost of the pure metal isotopes.

The magnitudes of metal isotope shifts are generally of the order of $2\text{--}10\text{ cm}^{-1}$ for stretching modes and $0\text{--}2\text{ cm}^{-1}$ for bending modes, whereas the experimental error in measuring the frequency could be as small as $\pm 0.2\text{ cm}^{-1}$.

In highly symmetrical molecules (T_d , O_h etc.), the central atom does not move during the totally symmetric vibration and no metal-isotope shifts are expected. When the central atom is coordinated by several donor atoms, multiple isotope labelling is necessary to distinguish different coordinate bond-stretching vibrations. For example, complete assignments of bis(β -diketonato)nickel(II) derivatives require $^{16}\text{O}/^{18}\text{O}$ as well as $^{58}\text{Ni}/^{62}\text{Ni}$ isotope shift data. The metal-isotope technique is often indispensable not only in assigning the metal–ligand vibrations but also in refining metal–ligand stretching force constants in normal coordinate analysis. The presence of vibrational coupling between metal–ligand and other vibrations can also be detected by combining metal-isotope data with normal coordinate calculations, since both experimental and theoretical isotope shift values will be smaller when such couplings occur.

The metal-isotope technique is very important in biological molecules such as haem proteins: structural and bonding information about the active site (iron porphyrin) can be obtained through definitive assignments of coordinate bond-stretching vibrations around the iron atom. Using resonance Raman techniques, it is possible to

observe iron porphyrin and iron-axial ligand vibrations without interference from peptide chain vibrations. Thus, these vibrations can be assigned by comparing a resonance Raman spectrum of a natural haem protein with that of a ^{54}Fe -reconstituted haem protein.

Inorganic Compounds

This and the following paragraphs are devoted to a general resumé of the more common and important spectroscopic and structural information on inorganic compounds: the assignment of the fundamental vibrations are based on point-group symmetry.

Diatomic molecules have only one vibration along the chemical bond: in homopolar AA ($D_{\infty h}$) molecules, this vibration is Raman active but not IR active, whereas the stretching vibration is both Raman and IR active in heteropolar AB ($D_{\infty v}$) molecules.

Table 3 lists some relevant observed frequencies for diatomic molecules, ions and radicals: the effect of the charge on the frequency in the series of the dioxygen species is worthy of note and also the vibrational frequencies characteristic of hydrogen halides which generally polymerize in the condensed phases. The HX stretching bands are shifted markedly to lower frequencies on polymerization.

IR and Raman spectra can be used to select between bent and linear structures in triatomic inorganic molecules (**Table 4**): the linear $X_3D_{\infty h}$ and XAX ($D_{\infty h}$)-type molecules have three normal modes (**Figure 6**), ν_1 , Raman active but not IR active, and ν_2 and ν_3 , IR active but not Raman active. In the case of bent X_3 (C_{2v}) and XAX (C_{2v})-type molecules, all three vibrations are IR and Raman active.

Pyramidal XY_3 (C_{3v}) molecules have four normal modes of vibration (**Figure 7**) (**Table 5**), all IR and Raman active, which have been used, for example, to confirm the presence of the hydronium (H_3O^+) ion in hydrated acids. Substitution of one of the Y atoms of a pyramidal XY_3 molecule by a Z atom lowers the

symmetry from C_{3v} to C_s . Then the degenerate vibrations split into two bands [$\nu_d(\text{XY}) \rightarrow \nu_s(\text{XY}) + \nu_a(\text{XY})$; $\delta_d(\text{YXY}) \rightarrow \delta_s(\text{YXY}) + \delta_a(\text{YXZ})$] (δ = bending), and all six vibrations become IR and Raman active (**Table 5**).

The four normal modes of vibration of planar XY_3 (D_{3h}) molecules are shown in **Figure 8**, whereas significant vibrational frequencies of planar XY_3 molecules are listed in **Table 5**. Pyramidal and planar structures can be distinguished easily on the basis of the difference in selection rules.

Tetrahedral XY_4 molecules have four normal modes of vibration (Figure 9) which are all Raman active, whereas only ν_3 and ν_4 are IR active. In XH_4 -type molecules (Table 6), the following trend is observed: $\nu_3 > \nu_1$ and $\nu_2 > \nu_4$. In MX_4 derivatives, the MX stretching frequency generally decreases on going from F to I. The average values of $\nu(MBr)/\nu(MCl)$ and $\nu(MI)/\nu(MCl)$ calculated from selected compounds are 0.76 and 0.62, respectively, for ν_3 , and 0.61 and 0.42, respectively, for ν_1 . These values are very useful in the assignment of the MX stretching bands in halogeno complexes.

The effect of changing the oxidation state on the MX stretching frequency has been extensively studied with $[FeX_4]^-$ and $[FeX_4]^{2-}$ ($X = Cl$ and Br) species: it has been found that the MX stretching frequency increases as the oxidation state of the metal increases. In tetrahedral MO_4^- , MS_4^- and MSe_4^- compounds, the ν_1/ν_3 ratio increases as the negative charge of the anion increases; for anions having the same negative charge and the central atom belonging to the same group of the periodic table, the ν_1/ν_3 ratio increases with increasing mass of the central atom, and finally the ν_1/ν_3 ratio increases with increasing negative charge of the anion in isoelectronic ions, with the mass of the central atom approximately constant.

^aDistorted, ν_7 : 388; ν_8 : 719; ν_9 : 319.**Figure 10** Normal modes of vibration for a square-planar XY_4 molecule.

XY_5 molecules may be trigonal bipyramidal (D_{3h}) or tetragonal pyramidal (C_{4v}). Trigonal bipyramidal structures have eight normal modes of vibration, six of which (A'_1 , E' and E'') are Raman active and five (A''_2 and E') are IR active. Normal coordinate studies have demonstrated that in neutral trigonal bipyramidal MX_5 compounds, the equatorial bonds are stronger than axial ones.

In tetragonal XY_5 molecules, the axial stretching frequency (ν_1) is generally higher than equatorial stretching frequencies (ν_2 , ν_4 and ν_7). This is the opposite of what is found for trigonal bipyramidal XY_5 molecules.

Figure 11 shows the six normal modes of vibration of an octahedral XY_6 molecule. Vibrations ν_1 , ν_2 and ν_5 are Raman active, whereas only ν_3 and ν_4 are IR active; ν_6 is inactive in both, and its frequency is estimated from an analysis of combination and overtone bands. Vibrational frequencies of several octahedral XY_6 molecules are reported in **Table 8**. The order of the stretching frequencies can be $\nu_1 > \nu_3 > \nu_2$ or $\nu_1 < \nu_3 > \nu_2$, depending on the compound.

The order of the bending frequencies is $\nu_4 > \nu_5 > \nu_6$ in most cases. In the same group of the periodic table, the

stretching frequencies decrease as the mass of the central atom increases.

Several XY_6 -type ions show splitting of degenerate vibrations due to lowering of symmetry in the crystalline state, an effect which has been attributed to a static Jahn–Teller effect.

Characteristic IR frequencies and their assignment for some other important anions are summarized in **Table 9**.

In some cases where there is high point group symmetry, vibrations normally IR inactive often appear as a weak band and doubly and triply degenerate vibrations can split into two and three components, respectively. These effects derive either from lowering of the point group symmetry or from factor group splitting as a result of different crystalline environments.

Coordination Compounds

Ammine Complexes

The NH_3 stretching frequencies in hexammine complexes (**Figure 12**) are generally lower than those in the free NH_3 molecule due to the fact that on coordination the N–H bond is weakened: the stronger the M–N bond, the weaker is the N–H bond and the lower are the NH_3 stretching frequencies. For this reason, the NH_3 stretching frequencies may be used as a rough measure of the M–N bond strength. The effect of the counterion should be considered: the NH_3 stretching frequencies in chloride derivatives are much lower than those in the perchlorate ones and the weakening of the N–H bond is due to the formation of the $\text{N–H} \cdots \text{Cl}$ -type hydrogen bond in the former. The main effect of coordination and hydrogen bonding is the shift to higher frequencies of the NH_3 deformation and rocking modes. The NH_3 rocking mode is most sensitive whereas the degenerate deformation is least sensitive to these effects.

Nitro, Nitrito and Nitrate Complexes

The NO_2^- ion is able to coordinate metals in a variety of ways (**Figure 13**), and vibrational spectroscopy is very useful in distinguishing the possible structures.

If the NO_2 group is bonded to a metal through its N atom (nitro form), it exhibits $\nu_a(\text{NO}_2)$ and $\nu_s(\text{NO}_2)$ in the 1470–1370 and 1340–1320 cm^{-1} regions, respectively. The free NO_2^- ion exhibits the same modes at 1250 and 1335 cm^{-1} , respectively; thus $\nu_a(\text{NO}_2)$ shifts markedly to a higher frequency, whereas $\nu_s(\text{NO}_2)$ changes very little on coordination.

However, if the NO_2 group is bonded to a metal through one of its O atoms (nitrito form), it shows two $\nu(\text{NO}_2)$ well separated at 1485–1400 cm^{-1} , $\nu(\text{N}=\text{O})$, and 1110–1050 cm^{-1} , $\nu(\text{NO})$, respectively. The nitrito complexes lack the wagging modes near 620 cm^{-1} which appear in all nitro derivatives and exhibit $\nu(\text{MO})$ ($\text{M}=\text{Cr}(\text{III})$, $\text{Rh}(\text{III})$ and $\text{Ir}(\text{III})$) in the 360–340 cm^{-1} region.

If the NO_2 group is O_2 -chelating, both antisymmetric and symmetric NO_2 stretching frequencies are lower and the ONO bending frequency is higher than that for unidentate N-bonded nitro complexes. In this case, $\nu_a(\text{NO}_2)$ depends on the degree of asymmetry of the coordinated nitro group: it is lowest when two N–O bonds are equivalent and becomes higher as the degree of asymmetry increases.

The nitro group is also known to form a bridge between two metal atoms (**Figure 13**) with NO_2 stretching bands appearing at 1492 and 1180 cm^{-1} . On isotopic substitution of the bridging oxygen, the latter is shifted by -10 cm^{-1} whereas the former is almost unchanged. For this reason, these bands have been assigned to the $\nu(\text{N}=\text{O})$ (outside the bridge) and $\nu(\text{N}-\text{O})$ (bridge), respectively.

**Figure 12** IR spectrum of the hexammine cobalt complex $[\text{Co}(\text{NH}_3)_6]\text{Cl}_2$.

The NO_3^- ion is able to coordinate in unidentate, symmetric and asymmetric chelating bidentate, and bridging bidentate fashion (**Figure 13**). It is very difficult to distinguish the possible structures by vibrational spectroscopy since the symmetry of the nitrate ion differs very little among them (C_{2v} or C_s). The unidentate NO_3 group exhibits three NO stretching bands, as expected due to its C_{2v} symmetry. For example, in $[\text{Ni}(\text{en})_2(\text{NO}_3)_2]$ containing unidentate nitrato groups the three bands at 1420, 1305 and 1008 cm^{-1} have been identified as $\nu_a(\text{NO}_2)$, $\nu_s(\text{NO}_2)$ and $\nu(\text{NO})$, respectively; whereas $[\text{Ni}(\text{en})_2\text{NO}_3]\text{ClO}_4$, which contains a chelating bidentate nitrate, exhibits the three bands at 1476 cm^{-1} , 1290 cm^{-1} and 1025 cm^{-1} , due to $\nu(\text{N}=\text{O})$, $\nu_a(\text{NO}_2)$ and $\nu_s(\text{NO}_2)$, respectively.

The separation of the two highest frequency bands is larger for bidentate than for unidentate coordination, a rule which is not applicable if the complexes are markedly different. For structural diagnosis, it is possible to use the combination band, $\nu_1 + \nu_4$, of free NO_3^- ion which appears in the $1800\text{--}1700\text{ cm}^{-1}$ region. On coordination, the ν_4 (E' , in-plane bending) near 700 cm^{-1} splits into two bands, and the magnitude of this splitting is expected to be larger for bidentate than for unidentate ligands. In some cases, this produces the separation of two ($\nu_1 + \nu_4$) bands in the $1800\text{--}1700\text{ cm}^{-1}$ region, the NO_3^- ion being bidentate if the separation is $70\text{--}20\text{ cm}^{-1}$ and unidentate if it is $25\text{--}5\text{ cm}^{-1}$.

**Figure 13** Coordination modes of the NO_2^- and NO_3^- ions.

Lattice Water

It is possible to classify water in inorganic salts and coordination compounds such as lattice or coordinated water,

but no definite borderline exists between the two forms. Vibrational spectra are often useful for providing information which allows the two forms to be distinguished.

Lattice water exhibits strong absorptions at 3550–3200 cm^{-1} (antisymmetric and symmetric OH stretchings) and at 1630–1600 cm^{-1} (HOH bending). In the region 600–200 cm^{-1} , lattice water exhibits ‘libration modes’ that are due to rotational oscillations of the water molecule.

Aquo and Hydroxo Complexes

The structure of aquo complexes is often assigned on the basis of their vibrational spectra: $\text{TiCl}_3 \cdot 6\text{H}_2\text{O}$ has been formulated as *trans*- $[\text{Ti}(\text{H}_2\text{O})_4\text{Cl}_2]\text{Cl} \cdot 2\text{H}_2\text{O}$ since it exhibits one TiO stretching (500 cm^{-1} , E_u) and one TiCl stretching (336 cm^{-1} , A_{2u}) mode.

In the Raman spectra of aqueous solutions of nitrate and sulfate zinc(II) and mercury(II) salts, the polarized Raman bands in the 400–360 cm^{-1} region have been assigned to the metal–O stretching modes of hexacoordinated aquo complex ions.

The hydroxo group can be distinguished from the aquo group since the former lacks the HOH bending mode near 1600 cm^{-1} , and hydroxo complexes exhibit MOH bending modes below 1200 cm^{-1} (e.g. 1150 cm^{-1} for the $[\text{Sn}(\text{OH})_6]^{2-}$ ion). The OH group is able to bridge two metal atoms: in $[(\text{bipy})\text{Cu}(\text{OH})_2\text{Cu}(\text{bipy})]\text{SO}_4 \cdot 5\text{H}_2\text{O}$ the bridging OH bending mode is at 955 cm^{-1} and is shifted to 710 cm^{-1} on deuteration.

Perchlorato Complexes

IR and Raman spectroscopy techniques have been used extensively to determine the mode of coordination of the ClO_4^- ligand. For example, the ionic $\text{K}[\text{ClO}_4]$ shows only two characteristic bands at 1170–1050 and 935 cm^{-1} , whereas $\text{Cu}(\text{ClO}_4)_2 \cdot 2\text{H}_2\text{O}$, where the perchlorate is coordinated in unidentate fashion, exhibits three strong absorptions at 1158, 1030 and 920 cm^{-1} . In the bidentate perchlorate complexes, the first absorption is split into three bands (1270–1245, 1130 and 948–920 cm^{-1}), whereas the second band appears at 1030 cm^{-1} .

β -Diketones

β -Diketones form metal chelates of type I, II, III and IV (Figure 14). The $\nu(\text{MO})$ of these chelates, assigned by using the metal-isotope technique, provides direct information about the M–O bond strength. Vibrational spectroscopy can be employed to differentiate *cis*- and *trans*-octahedral complexes $\text{M}(\text{acac})_2\text{X}_2$. For example, $\text{Ti}(\text{acac})_2\text{F}_2$ is ‘*cis*’ with two $\nu(\text{TiF})$ at 633 and 618 cm^{-1} , whereas *cis*- and *trans*- $\text{Re}(\text{acac})_2\text{Cl}_2$ can be isolated. In the IR spectrum, the *trans* isomer exhibits $\nu(\text{ReO})$ and $\nu(\text{ReCl})$ at 464 and 309 cm^{-1} , respectively, whereas each

Figure 14 Coordination modes of β -diketone ligands.

of these bands splits into two in the *cis* isomer: 472 and 460 cm^{-1} for $\nu(\text{ReO})$ and 346 and 333 cm^{-1} for $\nu(\text{ReCl})$.

In some derivatives, the keto form of acac forms a chelate ring (II). This kind of coordination has been observed in $\text{M}(\text{acacH})\text{Cl}_2$ ($\text{M} = \text{Co}$ and Zn) which exhibits a strong $\nu(\text{C}=\text{O})$ band near 1700 cm^{-1} .

In $\text{Mn}(\text{acacH})_2\text{Br}_2$, the acacH coordinates in the unidentate enolic form through only one O atom (III). The CO and CC stretching bands of the enol ring were found at 1627 and 1564 cm^{-1} , respectively.

In $[\text{Pt}(\text{acac})_2\text{Cl}_2]^{2-}$, the metal is bonded to the γ -carbon atom of the acetylacetonato ion (IV). The IR spectra show two $\nu(\text{C}=\text{O})$ at 1652 and 1626 cm^{-1} , two $\nu(\text{C}-\text{C})$ at 1350 and 1193 cm^{-1} , and one $\nu(\text{Pt}-\text{C})$ at 567 cm^{-1} .

Carbonyl Complexes

Carbonyl complexes generally exhibit strong sharp $\nu(\text{CO})$ bands between 2100 and 1800 cm^{-1} . Studies of $\nu(\text{CO})$ provide valuable information about the structure and bonding of carbonyl complexes because $\nu(\text{CO})$ is generally free from coupling with other modes and is not obscured by the presence of other vibrations. The $\nu(\text{CO})$ is generally at lower frequencies in the complexes than in the free CO (2155 cm^{-1}). However, the opposite trend is observed when CO is bonded to metal halides with the metals in a relatively higher oxidation state. Frequencies for bridging CO groups are much lower (1900–1800 cm^{-1}) than those of the terminal CO group (2100–2000 cm^{-1}), and extremely low $\nu(\text{CO})$ (approximately 1300 cm^{-1}) are observed when the bridging CO group forms an adduct through its O atom.

Vibrational studies on $\text{Fe}(\text{CO})_5$ and $\text{M}(\text{CO})_6$ ($\text{M} = \text{Cr}$, Mo and W) derivatives, including their ^{13}C and ^{18}O species, have indicated that the M–C bond strength increases in the order $\text{Mo} < \text{Cr} < \text{W}$, an order also supported by a Raman study.

It has been found that in the $M(CO)_4$ complexes (T_d), $\nu(CO)$ decreases and $\nu(MC)$ increases on going from $Ni(CO)_4$ to $[Co(CO)_4]^-$ to $[Fe(CO)_4]^{2-}$. This result indicates that the $M \rightarrow CO$ π back-donation increases in the order $Ni(0) < Co(-I) < Fe(-II)$. Highly reduced species such as $[W(CO)_4]^{4-}$ exhibit very low $\nu(CO)$ values ($1530\text{--}1460\text{ cm}^{-1}$).

Vibrational spectroscopy has been a subject useful for elucidating structures of polynuclear carbonyls. For $Co_2(CO)_8$, which has a structure containing six terminal and two bridging CO groups, five terminal and two bridging $\nu(CO)$ are expected to be IR active: the former are in fact observed at 2075, 2064, 2047, 2035 and 2028 cm^{-1} , whereas the latter are at 1867 and 1859 cm^{-1} .

In $MX(CO)_X$ derivatives ($X = Cl, Br$ or I), $\nu(CO)$ is highest for the chloro compound and lowest for the iodo compound (the bromo compound being between the two) in accordance with their electronegativities.

Dioxygen Complexes

Dioxygen (O_2) adducts of metal complexes have been extensively investigated with vibrational spectroscopy because of their importance as models for oxygen carriers in biological systems and as catalytic intermediates in oxidation reactions of organic compounds.

The bond order of the O–O linkage decreases as the number of electrons in the antibonding $2p\pi^*$ orbital increases: the bond order in $[O_2^+][AsF_6]$, O_2 , $K[O_2^-]$ and $Na_2[O_2^{2-}]$ is 2.5, 2.0, 1.5 and 1.0, respectively. This decrease causes an increase in the O–O distance and a decrease in the $\nu(O_2)$, which are at 1858, 1555, 1108 and 760 cm^{-1} , respectively.

An interesting example of dioxygen adducts of transition metal complexes is the *trans*-planar $[IrCl(CO)(PPh_3)_2]$ (Vaska's salt), which binds dioxygen reversibly to form a trigonal bipyramidal complex. The O–O distance of this compound ($1.30\text{ \AA}$) is close to that of the O_2^- ion ($1.28\text{ \AA}$): its $\nu(O_2)$ (857 cm^{-1}) is typical of peroxo adducts.

Halogeno Complexes

Halogens (X) are the most common ligands in coordination chemistry. Terminal MX stretching bands appear in the regions of $750\text{--}500\text{ cm}^{-1}$ for MF, $400\text{--}200\text{ cm}^{-1}$ for MCl, $300\text{--}200\text{ cm}^{-1}$ for MBr and $200\text{--}100\text{ cm}^{-1}$ for MI. The $\nu(MX)$ generally is higher with a higher oxidation state of the metal. In some cases, such as the $[M(dias)_2Cl_2]^{n+}$ ($dias = o$ -phenylenebis(dimethylarsine)), $\nu(MCl)$ changes rather drastically on going from Ni(III) (d^7) to Ni(IV) (d^6) (240 and 421 cm^{-1} , respectively), whereas very little change is observed between Fe(III) (d^5) and Fe(IV) (d^4) (384 and 390 cm^{-1} , respectively). This was attributed to the presence of one electron in the antibonding e_g^* orbital in the Ni(III) complex.

The SnX stretching force constants of halogenotin compounds are approximately proportional to the oxidation number of the metal divided by the coordination number of the complex. It is interesting to note that the $\nu(SnCl)$ of free $SnCl_3^-$ ion [289 (A_1) and 252 (E) cm^{-1}] are shifted to higher frequencies on coordination to a metal: the $\nu(SnCl)$ of $[Rh_2Cl_2(SnCl_3)_4]^{2-}$ are at 339 and 323 cm^{-1} .

The number of $\nu(MX)$ vibrations observed is often very useful for determining the stereochemistry of the complex: in the vibrational and Raman spectra of planar $M(NH_3)_2X_2$ [$M = Pt(II)$ and $Pd(II)$] the *trans* isomer (D_{2h}) exhibits one $\nu(MX)$ (B_{3u}), whereas the *cis* isomer (C_{2v}) exhibits two $\nu(MX)$ (A_1 and B_2) bands in the IR.

Some derivatives, such as $Ni(PPh_2R)_2Br_2$ ($R = \text{alkyl}$) exist in two isomeric forms, tetrahedral and *trans*-planar. Distinction between these two can be made easily since the numbers and frequencies of IR-active $\nu(NiBr)$ and $\nu(NiP)$ are different for each isomer: in fact, $\nu(NiBr)$ and $\nu(NiP)$ are at approximately 330 and 260 cm^{-1} , respectively, for the planar form, and at approximately $270\text{--}230$ and $200\text{--}160\text{ cm}^{-1}$, respectively, for the tetrahedral form.

IR data allows the differentiation of between *fac* and *mer* $[MX_3(L)_3]$ isomers: for example, *fac*- $[RhCl_3(Py)_3]$ gives two bands at 341 and 325 cm^{-1} , whereas *mer*- $[RhCl_3(Py)_3]$ shows three bands at 355 , 322 and 295 cm^{-1} .

Bridging MX stretching frequencies [$\nu_b(MX)$] are generally lower than terminal MX stretching frequencies [$\nu_t(MX)$].

Complexes Containing Metal–Metal Bonds

Complexes containing metal–metal bonds show $\nu(MM)$ in the low-frequency region ($250\text{--}100\text{ cm}^{-1}$) because the M–M bonds are relatively weak and the masses of metals are relatively large. In the IR, $\nu(MM)$ is forbidden if the complex is perfectly centrosymmetric with respect to the M–M. If the derivative is not centrosymmetric, a weak $\nu(MM)$ appears.

In heteronuclear complexes, the $\nu(MM')$ vibration is stronger than $\nu(MM)$ because of the presence of a dipole moment along the M–M' bond.

In Raman spectroscopy, both $\nu(MM)$ and $\nu(MM')$ appear strong since large changes in polarizabilities are expected as a result of stretching long, covalent M–M bonds. Several $\nu(MM)$ of polynuclear carbonyls have been reported, and the MM stretching force constants obtained from normal coordinate analysis have been used to discuss the nature of the M–M bond. For example, $(CO)_5Mn-W(CO)_5$ exhibits the $\nu(M-M)$ in the Raman spectra at 153 cm^{-1} .

Compounds containing unusually short M–M bonds exhibit unusually high $\nu(MM)$. The Mo–Mo distance in $Mo_2(OAc)_4$ is $2.09\text{ \AA}$, and the $\nu(MM)$ appears at 406 cm^{-1} because the Mo–Mo bond consists of one σ -bond, two π -bonds and a δ -bond (bond order 4).

Organometallic Compounds

Metal Alkanes

The methyl group bonded to a metal ($M-CH_3$) exhibits the six normal vibrations expected for tetrahedral ZXY_3 molecules. In addition, CMC bending and CH_3 torsional modes are expected for $M(CH_3)_n$ ($n \geq 2$) compounds. In $M(CH_3)_4$ derivatives ($M = Si$ or Sn), the CH_3 rocking, MC stretching and CMC bending frequencies are very sensitive to the change in metals, and the number of these skeletal IR or Raman active modes provides direct information about the structure of the MC skeleton.

Some metal alkyls are polymerized in the solid state: $Li(CH_3)$ forms a tetramer containing $Li-CH_3-Li$ bridges in the solid state and its CH_3 frequencies are lower than those of nonbridging compounds. The IR spectra of $Li[Al(CH_3)_4]$ and $Li_2[Zn(CH_3)_4]$ have been interpreted on the basis of linear polymeric chains in which the Al (or Zn) atom and the Li atom are bonded alternately through two CH_3 groups.

Metal Alkenes and Alkynes

A vinyl group σ -bonded to a metal ($M-CH=CH_2$) exhibits, in addition to the MC stretching and CMC bending modes, strong $C=C$ stretching vibrations in the Raman spectra. Their intensity and position in IR spectra depend on the metal: for example, $Hg(CH=CH_2)_2$ exhibits $\nu(C=C)$ at 1603 , and $\nu(MC)$ at 541 and 513 cm^{-1} .

Also, the $C\equiv C$ stretching frequencies of acetylenic compounds are strong in the Raman, but vary from strong to weak in the IR, depending on the metal involved. In contrast to σ -bonded complexes, the $C=C$ and $C\equiv C$ stretching bands of π -bonded complexes show marked shifts to lower frequencies relative to those of free ligands.

Alkenes form π -complexes with transition metals. Zeise's salt, $K[Pt(C_2H_4)Cl_3] \cdot H_2O$, has been extensively investigated, but assignments have been often controversial. Two types of bonding are involved in the $Pt-C_2H_4$ bond: a σ -bond formed by the overlap of the filled $2p\pi$ bonding orbital of the alkene with the vacant d_{sp^2} bonding orbital of the metal and a π -bond formed by the overlap of the $2p\pi^*$ antibonding orbital of the alkene with a filled dp hybrid orbital of the metal. If the σ -bond is predominant, bonding scheme I (Figure 15), which predicts one $Pt(II)$ -alkene stretching mode, should be preferred.

Some workers assigned the absorption at 407 cm^{-1} band of Zeise's salt to this mode. However, if bonding scheme II is operating, a five coordinate Pt atom is formed and the two bands at 491 and 403 cm^{-1} can be assigned to the symmetric and antisymmetric PtC stretching modes, respectively. The real bonding is somewhere between I and II, and the latter may become more significant as the

Figure 15 Possible bonding schemes for the $Pt-C_2H_4$ bond in Zeise's salt.

oxidation state of the metal decreases. In Zeise's salt X-ray analysis and MO calculations, together with IR studies suggest bonding scheme I.

Free $HC\equiv CH$ exhibits a CC stretching band at 1974 cm^{-1} . When coordinated as in $(HC\equiv CH)Co_2(CO)_6$, the CC stretching band was observed at 1402 cm^{-1} , which is approximately 570 cm^{-1} lower than the value for free acetylene. The spectrum of the coordinated acetylene in this complex is similar to that of free acetylene in its first excited state, in which the molecule takes on a *trans*-bent structure. Free $HC\equiv C(C_6H_5)$ exhibits the $C\equiv C$ stretching band at 2111 cm^{-1} . In the case of σ -bonded complexes, this band shifts slightly to a lower frequency (2036 – 2017 cm^{-1}), whereas, in $M[-C\equiv C(C_6H_5)]_2$ [$M = Cu(I)$ and $Ag(I)$], it shifts to 1926 cm^{-1} due to the formation of both σ - and π -type bonding.

Symbols

f	bond force constant (N m^{-1})
δ	bending mode frequency (cm^{-1})
μ	reduced mass
ν	stretching mode frequency (cm^{-1})

The vibrational spectra of organic compounds are typically complex, possessing many individual bands of variable intensity and shape. It is observed that certain bands are associated with specific chemical groups, that is, certain vibrational motions are largely concentrated within a portion of the molecule. Such bands are identifiable primarily by their occurrence within a narrow range of frequencies and their presence or absence from a spectrum allows empirical judgments to be made concerning the chemical structure. No chemical group, however, is completely isolated in vibrational or electronic terms, and therefore the exact frequency and intensity is determined by and can provide information about the adjacent chemical environment. Examination of many thousands of organic compounds has enabled numerous correlations to be established between elements of IR spectra and chemical structure and extensive tables of group frequency data are available in many publications. Although it is rarely possible to assign most of the bands in an IR spectrum, sufficient information can often be gleaned that, when allied with data from Raman spectra and other techniques, allows complete structural determination to a high degree of confidence. The concept of group frequencies underpins much of vibrational spectroscopy, though it is not necessary for quantitative analysis.

Initial Considerations and Definitions

Frequency and Wavenumber

IR absorption (or Raman shift) is caused by a quantum transition between two energy levels, and so band positions ought to be defined in terms of energy units. However, atoms can be treated as oscillating under the influence of spring-like bonds obeying Hooke's law, so the terms vibration and vibrational frequency are habitually used. The vibrational frequency is considered to be equal to the frequency of absorbed radiation (or

frequency difference in the case of Raman) and is proportional to the energy difference, but it is customary to define its value not in hertz but in a frequency-dependent unit, the wavenumber, cm^{-1} , which is the reciprocal of the spectral wavelength as measured in centimetres.

Differences between IR and Raman Spectroscopies

For a variety of reasons, IR spectroscopy is more fruitful than Raman for applying group frequencies to structural analysis. Some of these reasons are technical, for instance access to IR equipment is much easier and many compounds are not amenable to Raman spectroscopy with visible excitation (as used in the majority of instruments) owing to fluorescence or decomposition under laser illumination.

Chemical moieties that yield good group IR frequencies tend to be polar in nature and such entities tend not to give prominent bands in Raman spectra. Conversely, some elements of structure such as $\text{C}=\text{C}$ bonds, particularly if situated in largely symmetrical and non-polar surroundings, absorb very weakly in the IR, but in contrast are relatively strong in the Raman.

This complementary feature of Raman spectroscopy arises because it is change in *polarizability* during vibration that is important for determining intensity, rather than dipole change as in the IR. Confidence in assigning group frequencies is therefore often considerably strengthened by utilizing Raman spectroscopy if possible.

Overall molecular symmetry is rarely of importance in studying organic compounds as the vast majority of compounds do not possess any. However, local group symmetry usually has a bearing on the relative intensities of certain bands.

Physical State

In what follows, the listed frequencies are mostly for samples measured in liquid or solid phase. These can often be found to vary by a few wavenumbers owing to environmental conditions so that it is usually pointless to quote exact values. Care should be exercised with gas-phase frequencies as they can differ quite substantially, owing to the removal of intermolecular association effects. Hydrogen-bonded groups such as hydroxyl are particularly susceptible.

The Basis of Vibrational Frequency

For simple harmonic oscillation of a diatomic molecule the value of the vibrational frequency ν of the fundamental mode, in cm^{-1} , is given by the relationship

$$\nu = 130.3 \left(f \left[\frac{1}{m_1} + \frac{1}{m_2} \right] \right)^{1/2} \quad [1]$$

$$= 130.3 (f/\mu)^{1/2} \quad [2]$$

where f is the force constant (stiffness) of the bond in newtons per metre, m_1 and m_2 are the individual atomic masses (in atomic mass units) and μ is the 'reduced' atomic mass, which is given by

$$\mu = \frac{m_1 m_2}{m_1 + m_2} \quad [3]$$

A lone X–H bond (where X represents C, N, O, etc.) in a polyatomic compound vibrates almost as if it were a diatomic molecule. As μ in this case is always close to 1 and X–H bonds have broadly similar values of f , then the X–H moiety will yield a band in the same general region. For C–H, f is about 490 N m^{-1} , which yields a frequency of 3000 cm^{-1} ; actual values are usually 3100 – 2800 cm^{-1} . Frequencies for O–H and N–H are usually slightly higher owing to greater values of f .

The reduced mass of X–X' is rather larger than that of X–H, for instance for C–O μ is about 6.86 and since f here is roughly similar to that of C–H (both being single bonds) ν can be expected to be about $\sqrt{6.86}$ times less than 3000 cm^{-1} , i.e. about 1150 cm^{-1} . Double bonds are approximately twice as strong (and stiff) as single bonds, so C=O should 'vibrate' approximately $\sqrt{2}$ times more rapidly than C–O in the region around 1600 cm^{-1} . In fact, the 'average' carbonyl frequency is around 1700 cm^{-1} and for a variety of reasons, discussed below, can be found at least 100 cm^{-1} or so on either side of this value.

Likewise, triple bonds have values of f roughly three times greater than single bonds, thus C $\equiv$ C and C $\equiv$ N groups would be expected around 2000 cm^{-1} ; they are usually seen between 2300 and 2100 cm^{-1} or so.

The simplest case of a deformation or bending mode (given the symbol δ as opposed to ν which refers to stretching modes) involves a three-atom group with the atoms undergoing a scissors-like motion. Geometric considerations mean that the expression for μ is more complicated than, but not too different from, that for the diatomic oscillator, but the force constants are rather lower. Thus $\delta(\text{XH}_2)$ vibrations are broadly positioned in the region around 1500 cm^{-1} while $\delta(\text{XYH})$ occurs from 1500 to 1000 cm^{-1} and beyond. Deformations of XYZ (all C, N, O or heavier atoms) are below 1000 cm^{-1} .

The frequencies of stretching vibrations can usually be roughly predicted from knowledge of the bond order and the atomic masses. However, the values of the force constants involved in deformations are not obvious, so that their frequencies often appear to be rather arbitrary. The total number of vibrations for a nonlinear molecule is given by the relation, $3N-6$, where N is the number of atoms.

These simple considerations explain the general appearance of the vibrational spectra of organic chemicals. Essentially, most bands are found in two regions. First, from about 3600 to 2800 cm^{-1} , wherein lie features resulting from X–H stretching modes. Second, from about 1800 to below 400 cm^{-1} , a region densely occupied by bands from most other vibrations. The upper part, 1800 to about 1500 cm^{-1} , is often referred to as the double bond region, the rest as the fingerprint region. The region between 2800 and 1800 cm^{-1} is generally quite barren unless triple (or fused double) carbon–carbon or carbon–nitrogen bonds or one or two less common groups are present. Strongly hydrogen-bonded O–H and N–H can also produce features here. **Figure 1** provides an overview in chart form.

The IR spectra of inorganic compounds have a rather different aspect, consisting mostly of broad features at low frequencies. Although O–H and N–H are sometimes present, the spectrum down to about 1300 cm^{-1} is usually empty except for weak overtones and combination bands.

Finally, it will be obvious from the equations above that $\nu(\text{X–D})$, $\delta(\text{XD}_2)$ and $\delta(\text{XYD})$, where D is deuterium, will be considerably different in frequency from the corresponding vibrations with hydrogen.

Vibrational Interactions

No bond vibrates independently of any other in a polyatomic molecule, and where adjacent oscillators vibrate with similar or identical frequency, strong interaction takes place. This can be illustrated by considering the simple case of a symmetric linear triatomic molecule or group Y–X–Y, joined together by two equivalent bonds. When analysed in terms of classical mechanics the two individual oscillators couple mechanically together to yield two distinct modes of vibration with different frequencies. Representations of these modes are given in **Figure 2**.

The frequencies of each mode can be derived in a simplified fashion as follows. For the in-phase (or symmetric) mode, the central mass remains fixed in space so that each end atom is effectively joined to an infinite mass, thus:

$$\nu = 130.3 \left(f \frac{1}{m_Y} \right)^{1/2} \quad [4]$$

For the out-of-phase (antisymmetric or asymmetric) mode, the central mass is shared so that each end atom effectively vibrates independently with a central atom of

Figure 1 Correlation chart for vibrational spectra of organic compounds. The symbols ν and δ and X, Y and Z are defined in the text.

Figure 2 Representation of the two stretching modes of vibration of a linear triatomic molecule.

half mass, thus:

$$\nu = 130.3 \left(f \left[\frac{1}{m_Y} + \frac{2}{m_X} \right] \right)^{1/2} \quad [5]$$

The frequency of the isolated diatomic fragment Y-X is given by:

$$\nu = 130.3 \left(f \left[\frac{1}{m_Y} + \frac{1}{m_X} \right] \right)^{1/2} \quad [6]$$

By substituting some real values into the equations, it may be seen that the individual oscillators couple to produce two new frequencies, one considerably above and one considerably below the isolated oscillator frequency. **Table 1** gives the relevant bands of carbon disulfide ($\text{S}=\text{C}=\text{S}$) and allene ($\text{H}_2\text{C}=\text{C}=\text{CH}_2$) and the

theoretical ratios of their frequency values as calculated from eqns [4], [5] and [6]. For the case of allene, Y is treated as CH_2 with a mass of 14.

The strong coupling shown above takes place because the individual vibrators are identical. The less similar they are in terms of frequency, the lower will be the degree of coupling. This is revealed by consideration of the frequencies of simple triatomic linear cyanide molecules shown in **Table 2**. For HCN and the halogenides, the 'natural' (isolated) C-H or C-halogen frequencies are very different from $\nu(\text{C}\equiv\text{N})$ and there is little interaction, as demonstrated by the roughly constant values of the latter. But this is not so for DCN and TCN (T = tritium), where by extrapolation from $\nu(\text{C}-\text{H})$ the C-D and C-T oscillators would have natural frequencies of about 2430 and 2050 cm^{-1} respectively.

The Reality of Group Frequencies

It should be evident from the above that where two or more oscillators are strongly coupled, they will be highly sensitive to replacement or substitution of any individual units. The associated frequencies will therefore not be reliable indicators of particular items of chemical structure.

The observation that many simple groups are associated with bands that occur regularly in fairly narrow regions of the spectrum implies that they are largely

Table 1 Observed and calculated frequencies (cm^{-1}) for triatomic molecules $Y = X = Y$: carbon disulfide (CS_2) and allene (C_3H_4)

Note: The values for D and T are strongly coupled and are therefore mixed modes.

isolated in vibrational terms. This means that the frequencies are insensitive to gross changes in molecular structure elsewhere. This is understandable for a carbonyl group or a $\text{C}=\text{C}$ bond positioned in a singly bonded chain of carbon atoms, for instance. While individual vibrators within a group may couple strongly with each other, as long as they only couple weakly with external moieties, they retain their status as group frequencies.

Such characteristic and reliable frequencies provide a powerful means for identification of molecular subunits. By definition, they are largely insensitive to mechanical (vibrational) interactions and electronic effects from different adjacent atoms or groups. However, these perturbations can produce consistent shifts that are not so great as to destroy the characteristic nature of the group frequency, so that they provide information on the nature of the immediate chemical environment.

Mixed-Character Vibrational Modes

The modes of the linear triatomic molecule, described in the previous section, are purely bond stretching in character. In nonlinear molecules, such as H_2O , bond stretching leads to small changes in bond angles through electron redistribution, and the converse occurs for deformation modes. In these simple cases the degree of mixing of bend and stretch is not significant, so that the modes are easily distinguishable from each other.

However, where atoms are joined together in a small ring, neither bond stretching nor bond angle bending can take place without each significantly affecting the other

so that many of the modes are highly mixed in character. Such vibrations of the molecular framework are often termed ‘skeletal’ modes. Some idea of their complexity can be gained from **Figure 3** which shows how the individual atoms oscillate for the various modes of the benzene framework.

There are few good identifiable group frequencies below about 1000 cm^{-1} ; spectra here are usually dominated by very mixed carbon skeletal and $\text{C}(\text{H})_n$ rocking modes.

Some Examples of Group Frequencies

A few of the more common submolecular units are now discussed below. Space permits only a cursory treatment and the frequency values given are necessarily a compromise between figures quoted in various publications, which tend to differ slightly.

Hydrocarbons

The Methylene Group

This is shown schematically in **Scheme 1** together with a representation of its associated local modes of vibration. The two $\text{C}-\text{H}$ bonds are coupled to give two discrete stretching modes of vibration. Simple analysis shows that typically both overall dipole fluctuation and frequency are greater for $\nu(\text{asym})$, so that in IR spectra the higher component of such a band doublet has the greater intensity.

The exact position of each band and its relative intensity is dependent on the nature of the atoms to which the methylene group is connected. In simple hydrocarbons the bands are situated in very narrow ranges, 2925 ± 10 , 2855 ± 10 and $1465 \pm 15\text{ cm}^{-1}$, respectively. Shifts occur from the presence of other groups and Fermi resonance can often bring some confusion to the region.

When methylene is part of a cyclopropane ring, distortion of bond angles leads to increasing sp^2 character in the $\text{C}-\text{H}$ bonds and thereby increases in force constants. This leads to a rise in both $\nu(\text{asym})$ and $\nu(\text{sym})$, to over 3000 cm^{-1} .

Methylene also engages in external vibrations where the group, as an effectively rigid unit, oscillates with respect to other atoms to which it is connected. One such

Scheme 1

mode, called a 'rock', is shown below, and where more than four adjacent CH_2 groups form an extended hydrocarbon chain, a characteristic band appears in the IR spectrum near to 725 cm^{-1} . The band is essentially due to a mode where all the CH_2 groups are rocking in phase, see **Scheme 2**.

The methyl group

There are three stretching modes, two normally identical (degenerate) asymmetric modes, and one symmetric, with a similar relation of frequency and intensity as for

Scheme 2

methylene but displaced to higher wavenumber. Like methylene, again, they are situated in narrow ranges, 2960 ± 10 and $2870 \pm 10\text{ cm}^{-1}$, respectively, in simple hydrocarbons.

As with the stretching modes, there are two normally or nearly degenerate asymmetric deformation modes that usually overlap with $\delta(\text{CH}_2)$ when both groups are present, and a symmetric bending mode in the region $1380\text{--}1370\text{ cm}^{-1}$ for simple hydrocarbons. Substituents other than carbon can shift the latter frequency quite markedly (**Table 3**), while carbonyl instead raises the intensity.

Triatomic Groups

The presence of these groups is signalled by a number of characteristic bands, as shown in **Table 4**. The respective bands are well separated and stably positioned in their respective regions, and therefore provide easily identifiable group frequencies. Typically, in IR spectra, the highest frequency band, from $\nu(\text{asym})$, is the strongest or is roughly equal in intensity to $\nu(\text{sym})$, while the deformation mode or modes are the weakest. In Raman spectra, however, both δ and $\nu(\text{asym})$ are weak while $\nu(\text{sym})$ is very prominent.

The Carbonyl Group

The carbonyl group provides one of the best indicators for the IR spectrum yielding a strong band typically in the region between 1800 and 1650 cm^{-1} , though occasionally up to 100 cm^{-1} more on either side. It is also an exemplar for the various electronic factors that influence group frequencies.

The C=O bond is polarized owing to the tendency of the oxygen to attract electrons from carbon (inductive effect) and this gives the group some single-bond character, ($^+\text{C}-\text{O}^-$), when the substituents are, for instance, methyls. If one of these is replaced by an electron-withdrawing atom such as chlorine, then the effect is largely cancelled out so that bond order is more nearly 2.

Table 3 Symmetrical $\delta(\text{XH}_3)$ frequencies for various X-CH₃

X	$\delta(\text{CH}_3)$ (cm^{-1})
F	~1475
O	1455–1435
N	1430–1370
CF ₃	~1410
CCl ₃	~1385
Cl	~1355
B	1320–1290
Br	~1305
S	1325–1300
P	1310–1290
Se	~1280
Si	1280–1250

The bond is in consequence stiffer and its vibrational frequency higher (see **Scheme 3**).

Nitrogen, like chlorine, is also more electronegative than carbon but it affects the carbonyl frequency in the opposite sense because of the additional and dominant effect of mesomerism. Here the C=O loses some of its double-bond character, and is thereby weakened, owing to redistribution of electrons into the C–N bond, ($^-\text{O}-\text{C}=\text{N}^+$).

In the case of esters, the mesomeric effect is weak so that the inductive effect of electronegative oxygen dominates to raise the frequency, and for vinyl and aryl substituents on oxygen it is higher still.

Conjugation reduces frequency because of reduction of double-bond character. Single conjugation usually generates a lowering of about 20–30 cm^{-1} , double conjugation a little more; for example, diaryl ketones yield $\nu(\text{C}=\text{O})$ near 1660 cm^{-1} .

Noncyclic amides yield $\nu(\text{C}=\text{O})$ between 1690 and 1620 cm^{-1} and, if primary or secondary, have also one, slightly weaker, band from N–H bending at 1650–1620 cm^{-1} or 1550–1510 cm^{-1} , respectively.

Where carbonyl is part of a strained ring, its frequency is raised, probably as a consequence of several different effects, not just that of electron redistribution. For instance, simple lactams display in the regions illustrated in **Scheme 4**.

Table 5 lists the basic frequencies for the carbonyl group in some of its more commonly encountered chemical forms. It can be seen that the carboxylic acid frequency observed depends on the technique. This is because they are almost always (in liquid and solid states) dimerized (see **Scheme 5**) so that the IR band observed is from the coupled asymmetric mode while that in the Raman is from the symmetric one.

Scheme 3

Table 4 Group frequencies of triatomics

Group ^a	$\nu(\text{asym})$ (cm^{-1})	$\nu(\text{asym})$ (cm^{-1})	$\delta(\text{cm}^{-1})$	External vibrations (cm^{-1})
NH ₂	3500–3350	3400–3300	1650–1590	<900
aph NO ₂	1550–1530	1380–1350}	630–610	<700
aro NO ₂	1550–1470	1350–1310		
CO ₂ ⁻	1610–1550	1420–1380	?	
aph SO ₂	1330–1300	1150–1110}	610–545	<525
aro SO ₂	1370–1350	1170–1150		
R-SO ₂ (NH ₂)	1380–1310	1180–1140	?	

^aaph = aliphatic; aro = aromatic.

Where two carbonyls are coupled together as in anhydrides or imides the symmetric stretching mode is, unexpectedly, at higher frequency and the relative intensities of the IR bands are strongly dependent on the relative orientation of the groups. For noncyclic anhydrides the higher mode is the most intense, but for cyclic anhydrides and imides it is the weaker.

Alcohols, Ethers and Esters

The C–O stretching bands of these units, while coupled with and potentially obscured by other vibrations, can be identified by their relatively high intensity in IR spectra. For ethers, $\nu(\text{C–O})$ occurs over the range 1140–1080 cm^{-1} ; aliphatic alcohols can be anywhere between 1100 and 1000 cm^{-1} ; while aromatic examples are higher in frequency, but usually weaker in intensity, at 1260–1180 cm^{-1} . For esters, $\nu(\text{C–O})$ is between 1300 and 1150 cm^{-1} , the exact position being dependent on the nature of the substituents both on oxygen and on the carbon. A second band is also observed around about 1100 cm^{-1} or so and both can probably be regarded as

Scheme 4

having C–O stretching character coupled with adjacent C–C stretching vibrations. With regard to the higher frequency, simple acetates are generally 1250–1230 cm^{-1} , while longer-chain homologues are 1200–1190 cm^{-1} ; conjugation gives greater values, so that unsaturated compounds such as phthalates and benzoates yield a strong band between 1300 and 1260 cm^{-1} .

Multiple Bonds

Table 6 gives information for some multiple bond groups. Bands from the CC and CN groups, where isolated, show rather variable intensity in IR spectra and, particularly those from C=C, are often difficult to identify. By contrast, these moieties feature strongly in the Raman. The asymmetric stretching mode band of a fused double-bond group, however, is always strong in the IR and occurs in the triple-bond region; for example, CO₂ which absorbs at just above 2300 cm^{-1} .

Frequencies are rarely lowered by more than 50 cm^{-1} on conjugation, but an exception is the azo group, for which it can be reduced by almost 200 cm^{-1} .

Usually P=O is present as part of a larger group such as a phosphorous acid or a phosphate ester and this is often the case as well for S=O as in sulfonic acids. The double bond can be delocalized somewhat into adjacent P–O or S–O single bonds (particularly on ionization in salts) and coupling of their vibrations with neighbouring C–O or C–C bonds leads to several bands between 1300 and 800 cm^{-1} . These often provide good diagnostic information.

Scheme 5

^aOlefin.

^bSulfone.

^cIsonitrile.

Hydrogens attached directly to doubly or triply bonded carbons give stretching bands between 3100 and 3000 cm^{-1} , owing to the sp^2 nature of the C–H bond, and are therefore a good indicator of unsaturation. In olefins, out-of-plane $\delta(\text{C}=\text{C}-\text{H})$ modes are substitution dependent, *trans* substitution yields a strong IR band at 980–965 cm^{-1} , while for *cis* an IR band is seen at 730–650 cm^{-1} .

The Benzene Ring

Although the benzene ring is a relatively large entity, it nevertheless yields a number of very useful group frequencies. As in olefins, C–H stretching absorptions appear from 3100 to 3000 cm^{-1} . Between 1600 and 1450 cm^{-1} a number of bands appear; often as many as four can be distinguished. They are produced by what are essentially stretching modes of conjugated C=C bonds with some contributions from in-plane C–C–H bending motions.

The most prominent IR bands are substitution sensitive and occur below 1000 cm^{-1} . Table 7 lists the relevant frequencies. Bands above 730 cm^{-1} are from out-of-plane C–C–H bending (C–H wag) modes, while those below are from ring bending.

Raman spectra of benzene rings show a strong very characteristic band in the 1000 cm^{-1} region. For benzene itself this comes from a ring breathing mode, but in substituted rings it is derived from other modes.

Heterocyclic aromatic compounds show some similarity to benzene and its homologues.

Halogens

Halogenated organics do not give good group frequencies. Bands from carbon–halogen stretching are spread across quite wide ranges; $\nu(\text{C}-\text{F})$ is anywhere from 1350 to 1000 cm^{-1} , while for C–Cl, C–Br and C–I stretching bands are 1100–500 cm^{-1} . Where carbon is aromatic, the frequencies tend to be higher than for aliphatic in each case. With the exception of fluorine (in the IR), the bands are of medium intensity so that it is difficult to differentiate them from the multitude of others in these regions.

Hydroxyl and N–H Stretching Bands

Both O–H and N–H moieties generally form intra- and intermolecular hydrogen bonds and their bands therefore

occur over a fairly wide range of wave-numbers below the position of the unbonded frequencies. Usually this is no more than 200–300 cm^{-1} , but in extreme cases such as carboxylic acids or ionized N–H or where tautomerism occurs, the shift can be rather larger.

In this sense they are not good group frequencies; however, hydrogen bonding broadens the width and raises the intensity of the bands in the IR so they can normally be recognized though not definitively assigned to one or other. Figure 4 shows part of the IR spectrum of *meta*-chlorobenzoic acid where $\nu(\text{O}-\text{H})$ is represented by the diffuse underlying absorption between about 3500 and 2500 cm^{-1} .

Group Frequencies in Spectral Interpretation and Structure Determination

Some IR spectra are presented below as examples. Band assignments are given in the figure captions.

Figure 5 shows the spectrum of isobutyl methyl ketone. The position of the carbonyl, while suiting a ketone, is also consistent with conjugated ester and carboxylic acid, but other characteristic bands from these two groups are not present.

Figure 6 is from benzyl alcohol ($\text{Ph}-\text{CH}_2-\text{OH}$). The hydroxyl bands are dominant despite only one O–H to seven C–H vibrators; this is due mainly to the effects of

Figure 4 Part of the IR spectrum of *meta*-chlorobenzoic acid. The bandlets between 2700 and 2500 cm^{-1} are a typical part of such broad bands and are derived from interactions (Fermi-resonance) with combinations and overtones from lower-frequency vibrations.

Table 7 Substitution sensitive bands of benzene below 1000 cm^{-1}

Substitution pattern	Band (s) (cm^{-1})
Mono	770–730 and 710–690
Ortho	765–735
Meta	790–770 and 705–685
Para	860–800

Figure 5 Band assignments for the IR spectrum of isobutyl methyl ketone: 2960 cm^{-1} , 2875 cm^{-1} , $\nu(\text{CH}_3)$ asym, sym; 1720 cm^{-1} , $\nu(\text{C=O})_g$; 1470 cm^{-1} , $\delta(\text{CH}_3)$ asym, $\delta(\text{CH}_2)$; 1370 cm^{-1} , $\delta(\text{CH}_3)$ sym; 1170 cm^{-1} , $\nu(\text{CCC})$ asym of $-\text{CH}_2-\text{C}(=\text{O})-\text{CH}_3$ unit.

Figure 6 Band assignments for the IR spectrum of benzyl alcohol ($\text{Ph}-\text{CH}_2-\text{OH}$): 3340 cm^{-1} , $\nu(\text{O-H})$; 3060 cm^{-1} , 3030 cm^{-1} , $\nu(\text{C-H})$ benzene ring; 2930 cm^{-1} , 2880 cm^{-1} , $\nu(\text{CH}_2)$ asym, sym; 1495 cm^{-1} , $\nu(\text{C=C})$ benzene ring; 1455 cm^{-1} , $\delta(\text{CH}_2)$; 1420 cm^{-1} , $\delta(\text{COH})$; 1020 , $\nu(\text{C-O})$; 740 cm^{-1} , 700 cm^{-1} , $\delta(\text{CCH})$ monosubstituted benzene ring.

hydrogen bonding. The aromatic bands are all consistent with or indicative of single substitution, including four from combinations of lower-frequency modes (not labelled) between 2000 and 1700 cm^{-1} . These latter are usually too weak to be of use in any other than simple molecules.

Figure 7 is from cinnamitrile ($\text{Ph}-\text{CH}=\text{CH}-\text{C}\equiv\text{N}$). The position of the nitrile band at 2220 cm^{-1} is indicative of conjugation.

Figure 8 shows *para*-nitroaniline. The polar substituents dominate, but some aromatic bands can still be seen.

Finally, **Figure 9** shows acetanilide ($\text{Ph}-\text{NH}-\text{C}(=\text{O})-\text{CH}_3$). The 3300 cm^{-1} band could suit $\nu(\text{O-H})$ but there is no obvious $\nu(\text{C-O})$ band. The strength of the 1600 cm^{-1} band is typical of anilino N-H bending rather than a purely benzene ring mode.

Figure 7 Band assignments for the IR spectrum of cinnamitrile ($\text{Ph}-\text{CH}=\text{CH}-\text{C}\equiv\text{N}$): 3060 cm^{-1} , 3030 cm^{-1} , $\nu(\text{C}-\text{H})$ benzene ring; 2220 cm^{-1} , $\nu(\text{C}\equiv\text{N})$; 1620 cm^{-1} , $\nu(\text{C}=\text{C})$ exocyclic; 1575 cm^{-1} , 1495 cm^{-1} , 1450 cm^{-1} , $\nu(\text{C}=\text{C})$ benzene ring; 965 cm^{-1} , $\nu(\text{C}=\text{C})$ *trans* substituted; 750 cm^{-1} , 695 cm^{-1} , $\delta(\text{CCH})$ mono-substituted benzene ring.

Figure 8 Band assignments for the IR spectrum of *p*-nitroaniline: 3480 cm^{-1} , 3360 cm^{-1} , $\nu(\text{NH}_2)$ asym, sym; 1630 cm^{-1} , $\delta(\text{NH}_2)$; 1605 cm^{-1} , $\nu(\text{C}=\text{C})$ benzene ring; 1475 cm^{-1} , 1320 cm^{-1} , $\nu(\text{NO}_2)$ asym, sym; 840 cm^{-1} , $\delta(\text{CCH})$ *para*-disubstituted benzene.

In these cases, structure has been assumed and band assignment is therefore definitive. Where a compound is unknown, assignments must initially be tentative and an iterative procedure has to be followed until all attributions are consistent with one another and with any other relevant information. With luck, confirmation may be possible by matching to a spectrum in a database, bearing in mind minor but not significant spectral differences due to different measurement conditions.

There are number of commercial databases with facilities for computer searching. The Sadtler collection of

organic compounds contains nearly 100 000 IR and several thousand Raman spectra.

Some Other Uses of Group Frequencies

Group frequencies are also useful in examining secondary effects and structure.

A simple example of physicochemical influence is provided by phenylalanine, whose IR spectrum is shown in **Figure 10**. This compound is a β -aminocarboxylic acid

Figure 9 Band assignments for the IR spectrum of acetanilide (Ph-NH-C(=O)-CH_3): 3300 cm^{-1} , $\nu(\text{N-H})$; 1665 , 1555 , $\nu(\text{C=O})$, $\delta(\text{CNH})$ secondary amide; 1600 cm^{-1} , $\delta(\text{CNH})$; 1370 cm^{-1} , $\delta(\text{CH}_3)$ sym; 755 cm^{-1} , 695 cm^{-1} , $\delta(\text{CCH})$ monosubstituted benzene ring.

Figure 10 IR spectrum of phenylalanine. Band assignments are given in the text.

(Scheme 6), but while the general appearances of the $3300\text{--}2500\text{ cm}^{-1}$ region could be suggestive of the broad diffuse absorption yielded by $\text{-CO}_2\text{H}$ (Figure 4), there is no obvious carbonyl frequency in the right place nor are there any distinct $\nu(\text{NH}_2)$ bands in the $3500\text{--}3350\text{ cm}^{-1}$ region. Instead, carboxylate is indicated by bands at 1565 and 1410 cm^{-1} . The broad higher-frequency absorptions around 3000 cm^{-1} are thus consistent with, and evidently from, ionized N(H) groups, in this case NH_3^+ . The compound therefore exists as an internal salt, or zwitterion.

A more complex case is that of secondary structure in large polypeptides and proteins. These molecules can assume a wide variety of conformations that often include large sections of regular structure where the backbone is arranged in the form of either the α -helix or the β -sheet. Vibrational spectra of proteins typically show that the amide carbonyl group is represented by several broad and overlapping bands that are spread over a range of frequencies, $1690\text{--}1610\text{ cm}^{-1}$, rather larger than can be explained by the presence of

**Scheme 6**

different amino acids. Vibrational coupling/electronic effects from the different side chains would only be expected to shift $\nu(\text{C}=\text{O})$ by a few wavenumbers.

This multiplicity of bands arises instead because of coupling along the polypeptide backbone, dipole–dipole interactions between carbonyl groups and hydrogen bonding between $\text{C}=\text{O}$ and $\text{N}-\text{H}$ groups, all of which are modified by differences in the secondary structure. Thus, amidic $\nu(\text{C}=\text{O})$ from alpha-helix is found about $1660\text{--}1645\text{ cm}^{-1}$ and from beta-sheet between 1640 and 1625 cm^{-1} . Disordered structures produce bands above 1670 and below 1630 cm^{-1} .

Comparison of IR and Raman Spectroscopy with Other Techniques

Vibrational spectroscopy provides particular insights into molecular structure but rarely a completely clear view. X-ray crystallography can provide absolute determination of structure but is expensive and limited to small compounds that will crystallize. Mass spectrometry (MS) can give the empirical formula, but identification of groups is dependent on the somewhat arbitrary way the molecule fragments. Nuclear magnetic resonance spectroscopy (NMR), the most powerful and popular structural technique nowadays, while very good at determining many of the finer points of structure, is limited in practical terms by the types of nuclei that will give useful spectra.

Fortunately, these spectroscopic techniques complement each other and it is therefore sensible to utilize them all for complete structural determination of unknowns. A particular strength of IR spectroscopy is that it provides easily the best method for initially surveying a completely unknown material. Physical state or solvation

properties are generally not a problem as they can be for MS or NMR in obtaining a spectrum (although aqueous conditions can be a confounding factor due to the strong IR absorption of water). Moreover, it is immediately apparent whether the sample is organic or inorganic (or a mixture) and what the major groups are likely to be.

Introduction

Over the past 30 years, Fourier transform IR (FT-IR) spectrometers have almost entirely replaced dispersive instruments. The most significant feature of FT spectrometers is that radiation from all wavelengths is measured simultaneously. This is much more efficient than the dispersive spectrometer where different wavelengths are measured successively. This difference, known as the Fellgett advantage, leads to much faster or more sensitive measurement. For example, a dispersive spectrometer typically takes at least 3 min to scan from 4000 to 400 cm^{-1} , whereas most FT instruments can acquire a spectrum in 1 s or less. The first commercial mid-IR FT spectrometer was introduced in 1969, but initially, the cost of the necessary computing power confined the use of such instruments to research applications. More recently, FT-IR spectrometers have become less expensive in real terms than the dispersive instruments that they have replaced. As this article will deal with instruments that are capable of recording complete spectra, it will not consider laser-based measurements.

The IR Region

The IR region covers wavelengths from approximately 800 nm to 1 mm. However, spectroscopists generally divide this region into three: near IR (NIR), from the visible to 2.5 μm ; mid IR, from 2.5 to 25 μm ; and far IR (FIR), beyond 25 μm (Figure 1). The main significance of this division is that most fundamental molecular vibrations occur in the mid IR, making this region the richest in chemical information. The NIR region contains

overtones and combinations of the fundamental vibrations, especially those involving hydrogen atoms. Some electronic absorptions are also found in this region. The FIR region is mostly of interest for vibrations involving heavy atoms, lattice modes of solids, and some rotational absorptions of small molecules.

This article will concentrate on the mid-IR region, which covers the widest range of applications. However, it is worth noting that interest in the NIR region has increased steadily in recent years.

Dispersive IR Spectrometers

The principle of operation of a dispersive spectrometer is very simple. A beam from a broadband source of radiation is dispersed by a prism or grating. The dispersed radiation falls on a slit through which a narrow range of wavelengths passes to reach a detector. Rotating the prism or grating brings successive wavelengths onto the slit, so scanning the spectrum. For the mid IR, the source is a ceramic rod or wire heated to around 1300 K. In practice, instruments use one or more gratings to cover the mid-IR region with filters to separate different orders of diffraction. The most common detector used to be a thermocouple, but the few current models use deuterated triglycine sulfate (DTGS) detectors. Instruments operate in a double-beam mode (Figure 2), switching rapidly between two equivalent optical paths, one of which contains the sample. The transmission of the sample is measured from the ratio between the detector signals from the two beams directly (ratio recording) or by moving an attenuator into the reference beam until the detector signal matches that through the sample.

Fourier Transform Spectrometers

Most commercial FT spectrometers are based on the Michelson interferometer (Figure 3). A collimated beam

Figure 1 The divisions of the IR region.

Figure 2 The optical arrangement of a double-beam dispersive IR spectrometer.

Figure 3 The basic optics of a Michelson interferometer.

Figure 4 The interference of overlapping cosine waves.

of radiation falls on a beam splitter that divides it into two beams with approximately equal intensities. These two beams strike mirrors that return them to the beam splitter where they recombine, creating interference, and then proceed to a detector. Moving one of the mirrors creates a varying optical path difference (OPD) between the two beams. As the path difference changes, the two beams move in and out of phase with each other, so that there is alternating constructive and destructive interference.

Monochromatic radiation produces a sinusoidal signal, the frequency of which is directly proportional to the wavenumber. The signal from a broadband source consists of a combination of overlapping sinusoidal signals, called an interferogram. A typical interferogram has a strong signal, called the centerburst, at the point where

the paths of the two beams are equal, and decays as the path difference increases (**Figure 4**). The interferogram can be converted into the required spectrum of intensities at different wavenumbers by an FT (**Figure 5**).

Unlike dispersive spectrometers, FT instruments operate in a single-beam mode (**Figure 6**). The sample is normally placed between the interferometer and the detector, in contrast to the arrangement in dispersive spectrometers, where the sample is placed between the source and the monochromator. Two spectra are recorded, first of the instrument alone and then with the sample in place. The ratio of these, calculated automatically, is the transmission spectrum of the sample (**Figure 7**).

Figure 6 The optical arrangement of an FT-IR spectrometer.

Figure 7 Single-beam spectra and the resulting sample spectrum.

Range and Resolution in FT-IR Spectrometers

The detector in an FT spectrometer sees a range of frequencies that is limited by the output of the source and the transmission of the optics. The interferogram is digitized before the Fourier transformation. The range of frequencies that can be identified in the Fourier analysis depends on the spacing of the data points in the digitized signal. There must be at least two data points for each

cycle of the highest frequency in the analysis. This is known as the Nyquist criterion. If there are fewer than two data points per cycle, the signal is indistinguishable from that of another, lower frequency, a phenomenon known as aliasing. Optical or electrical filtering is therefore needed to remove any frequencies that are above the Nyquist limit (**Figure 8**).

The resolution in the spectrum depends on the spacing of the frequencies provided by the FT. This is determined by the length of the interferogram. The frequencies used in an FT are such that an exact number of cycles fit the length of the interferogram from zero to the maximum OPD, Δ (in centimeters). Two adjacent frequencies in the analysis, corresponding to wavenumbers ν_1 and ν_2 , have n and $(n+1)$ cycles in this length. The wavenumbers are given by:

$$\nu_1 = n/\Delta \text{ and } \nu_2 = (n+1)/\Delta$$

From this, it follows that the difference between the wave numbers is:

$$\nu_2 - \nu_1 = 1/\Delta$$

Thus the spectrum generated by the FT contains wave numbers separated by the inverse of the maximum path difference in centimeters. Instruments for routine analytical work typically have highest resolution of 1 or 0.5 cm^{-1} , requiring a maximum path difference of 1 or 2 cm. This resolution is constant across the spectrum. Research instruments have been built with resolutions as

Figure 8 A signal sampled at less than two points per cycle and a lower frequency with identical values at the sampling points.

high as 0.0009 cm^{-1} , which requires a path difference in excess of 10 m.

In a practical instrument, the beam passing through the interferometer cannot be perfectly parallel. There are rays at different angles, and these experience different changes in the pathlength for a given displacement of the moving mirror. This causes line broadening by an amount that is proportional to the wavenumber. The range of angles admitted to the interferometer has to be restricted so that the required resolution is achieved. Incorporating an aperture, called a Jacquinot stop, at an appropriate point in the optical system controls this. In some ways, this aperture is analogous to the slit in a dispersive spectrometer. For a given resolution, the optical throughput of an FT spectrometer, limited by a circular aperture, can be higher than that of a dispersive spectrometer with a rectangular slit. This is referred to as the Jacquinot advantage and contributes to the higher sensitivity of FT instruments. The size of this aperture depends on the resolution and the wave number range. Lowering the resolution by a factor of two allows the energy reaching the detector to be doubled. However, in most spectrometers, it is not possible to increase the energy above that permitted for 4 cm^{-1} resolution because of other limitations such as the range of the analog-to-digital converter (ADC).

Measuring the Interferogram

To establish the wavelength scale of the spectrometer, the interferogram has to be measured at precisely known intervals of the path difference. Generally, this is achieved by using a helium–neon laser at $0.6328\text{ }\mu\text{m}$ ($15\,800\text{ cm}^{-1}$) to provide a reference signal. The laser radiation passes through the interferometer to a separate detector. This produces a sinusoidal signal with a period

equal to the wavelength of the laser (**Figure 9**). Typically, the interferogram signal is measured at each point where the laser signal passes through zero. With this spacing of the data points in the interferogram, all wave numbers below $15\,800\text{ cm}^{-1}$ can be distinguished. The laser wavelength is known very accurately and is very stable. As a result, the wavelength scale of FT spectrometers is much more accurate than that of dispersive instruments. This superiority is known as the Connes advantage, after the originator of the laser referencing technique. The absolute accuracy of the scale depends on the spectrometer resolution, whereas the scan-to-scan precision is of the order of 0.01 cm^{-1} . Semiconductor diode lasers have recently been used to build very compact FT-IR instruments. They lack the absolute wavelength stability of helium–neon lasers but can achieve scan-to-scan precision of 0.1 cm^{-1} , which is adequate for many applications.

The data points in the interferogram generally correspond to the path differences at which the signal from the laser passes through zero. In earlier instruments, analog electronics detected when this happened and triggered an ADC to collect the IR signal. More recently, all-digital systems have adopted ADCs developed for consumer audio and video products. They cannot be triggered but have superior linearity and 24-bit resolution, which significantly reduces noise and improves ordinate accuracy. There are two synchronized ADCs: one for the laser and one for the IR signal. The sinusoidal laser signal is measured many times each cycle, so the zero-crossing points can be determined very accurately by curve fitting. The digitized IR signal is then interpolated to find the value at these points (see **Figure 9**).

The time taken for an interferometer to scan from zero to the maximum path difference is typically of the order of 1 s. For most routine measurements, the interferogram

Figure 9 Locating the laser signal zero crossings by curve fitting and calculating the interferogram points by interpolation.

signal is averaged over several scans to reduce random noise that is largely generated by the detector. By averaging N scans, the noise level in the final spectrum can be reduced by a factor of $N^{1/2}$ relative to that from a single scan. For the signal averaging to work properly, the interferogram must be digitized with sufficient precision to record the noise in a single scan. The ADC must be able to handle the very large centerburst and the much smaller noise component. The precision needed for this is at least 16 bits.

In an ideal interferometer, the complete spectral information could be obtained by scanning the path difference from zero to the value needed to achieve the required resolution. However, data have to be measured for a limited distance on both sides of the nominal point of zero path difference to carry out phase correction. For signal averaging, the data points corresponding to the same path difference for successive scans have to be combined. The laser signal measures changes in the path difference but *not* its absolute value. In early FT instruments, this was measured by including a broadband white-light source, the interferogram from which is a very sharp spike at zero path difference (**Figure 10**). The optics were arranged so that zero path difference for the white light was offset from that for the IR radiation. The white-light signal was used to trigger data collection. The interferometer scans in one direction and collects a complete interferogram on one side of zero path difference only. After each scan, the interferometer would move back past the starting position to begin the next scan. Such

a scheme is described as unidirectional single-sided scanning (**Figure 11**). It was necessary to trigger each scan separately because the path difference could not be tracked through the change of direction at the end of the scan. Most systems now use two detectors with a phase shift between them to monitor the laser signal, allowing forward and reverse motion to be distinguished. This quadrature detection arrangement can continuously track the path difference and so control the coaddition of successive scans without individual triggering. It also allows the interferometer to collect data from scans in both directions. This bidirectional scanning achieves more efficient data collection as there is no fly-back period between scans.

Processing the Interferogram Signal

The signal processing to convert the interferogram into a spectrum usually involves phase correction, zero-filling, and apodization as well as the FT. An ideal interferogram would be perfectly symmetrical about zero path difference. However, in practice, there is some asymmetry because of phase differences between the signals from different wavenumbers. A phase correction routine is applied before the FT. Phase correction can be avoided by scanning the full length of the interferogram on both sides of zero path difference. This allows a magnitude spectrum to be calculated without phase correction. The FT itself uses the fast Fourier transform (FFT) algorithm

Figure 10 The use of a white-light interferogram to trigger data collection.

Figure 11 Alternative scanning and data collection schemes.

devised by Cooley and Tukey. This algorithm requires that the number of points to be transformed be equal to a power of two. However, the number of data points collected by scanning to a path difference of 1 cm, for example, does not correspond to a power of two. The interferogram is therefore extended by additional data points with the value of zero to give the required number of points. This process is called zero-filling. It is a common practice to apply further zero-filling to double or quadruple the number of points used. This improves the appearance of the final spectrum by increasing the

density of the data points, although it does not improve the resolution. In some systems, interpolation in the spectrum is used to give results that are equivalent to the additional zero-filling.

Apodization is an operation that is necessary because of the finite length of the interferogram. Monochromatic radiation produces a sinusoidal interferogram, but the length of this is limited by the maximum path difference in the interferometer scan. The FT of such a signal is a line of finite width with oscillations on either side. This line has the form of a sinc function ($\sin x/x$) (**Figure 12**).

The oscillations (or sidelobes) that accompany each line are obviously a problem because they could obscure smaller features in the spectrum. They can be reduced at the expense of some broadening of the lines by multiplying the interferogram with a function that decreases with increasing path difference. This process is called apodization. Various functions are used for this,

Figure 12 The sinc function generated by Fourier transformation of a cosine wave of finite length.

representing different compromises between line broadening and the reduction of the sidelobes. Historically, a simple triangular function was often used, but other functions can reduce the sidelobes further with less broadening. By examining a very large number of alternative functions, Norton and Beer established empirical limits for the reduction in sidelobe intensity that could be achieved for a given increase in linewidth. Three functions identified by Norton and Beer are in common use: weak, medium, and strong, corresponding to increasing degrees of sidelobe reduction and line broadening (**Figure 13**). The use of no apodization to achieve the narrowest possible lines is called boxcar truncation.

Scanning Mechanisms

To create interference, the beams returned from the two mirrors in the interferometer must overlap exactly as they meet at the beam splitter. Any change in the alignment of the mirrors reduces the efficiency of the interference by an amount that increases with the square of the wave number. Small mechanical changes, for example, associated with thermal expansion, can cause the alignment to change slowly. Changes that occur between

Figure 13 Some common apodization functions and the resulting lineshapes.

Figure 14 A parabolic baseline caused by misalignment of the interferometer.

measuring the background and sample spectra result in a curved baseline (**Figure 14**).

The scanning mechanisms of interferometers have to be designed to minimize any change in alignment during the scan that would introduce noise or distortion into the spectrum. In systems where a plane mirror moves linearly, the problem is to avoid any tilting of the moving mirror. In some spectrometers, the alignment is monitored and corrected continuously in a process called dynamic alignment. Multiple detectors measure the laser reference signal from different points in the beam. Any mirror tilt introduces a phase shift between the signals from the detectors because the path differences are not equal. This is automatically corrected in real time by using piezoelectric transducers to tilt the nonscanning mirror. The problem can also be addressed by using a cube-corner reflector instead of a plane mirror. Tilting the cube corner does not alter the direction of the reflected radiation, but lateral movement would affect the alignment. There are also scanning arrangements that completely avoid alignment errors during scanning. One of the simplest generates the path difference by rotating a pair of parallel mirrors in one arm of the interferometer (**Figure 15**). The mirror pair does not alter the direction of radiation passing through it, whatever its orientation, so that it cannot affect the alignment as it rotates.

Some commercial instruments use a scanning mechanism that does not involve moving mirrors. Changing the refractive index instead of the physical length can alter the optical path. By moving a wedge of a material such as KBr into one arm of an interferometer and displacing air, the optical path is increased. Because the mechanical tolerances are less severe than for simple moving mirror systems, these instruments are mostly used in nonlaboratory applications. One disadvantage is that the refractive index varies with wavelength so that the wavenumber scale is not inherently linear as it is in conventional instruments.

The range covered by a spectrometer depends primarily on the properties of the source and the beam splitter, and is sometimes limited by the detector. The sources used in mid-IR spectrometers typically operate at temperatures around 1300 K. Their output has a fairly similar profile to a black body and so provides significant energy across the entire mid-IR region. An ideal beam splitter would provide uniform reflectivity of 50% and no absorption across the region of interest. In practice, a single beam splitter made from KBr with a multilayer coating can be used from the NIR to approximately 400 cm^{-1} , where KBr absorbs strongly. Most interferometer designs incorporate a compensator plate so that both beams pass through the same thickness of KBr. An FT spectrometer can cover the entire mid-IR region in a single measurement. As can be seen from **Figure 16**, the single-beam energy falls off toward the ends of the range. In consequence, the noise level in the final spectrum increases at either end.

Detectors

For routine measurements, the most common detector material is DTGS. This is a thermal detector, the signal

Figure 16 The instrument profile for a mid-IR spectrometer and the resulting variation of the noise level.

Figure 15 A scanning mechanism with a rotating mirror pair.

being generated in response to the change in temperature caused by absorption of the IR radiation. It is generally operated at a temperature close to ambient. The response time of these detectors is less than 1 ms, allowing them to follow changes occurring at rates up to several kilohertz. In spectrometers with DTGS detectors, the OPD is typically scanned at approximately 0.3 cm s^{-1} because faster scanning would reduce the response of the detector. The time taken to scan the 0.25 cm needed for a spectrum at 4 cm^{-1} resolution is therefore approximately 1 s. Lithium tantalate is an alternative room-temperature detector material with somewhat lower performance but also lower cost.

When higher speed or sensitivity is needed, liquid nitrogen-cooled MCT (mercury cadmium telluride) detectors are used. These are photon detectors in which electrons are excited directly by the absorption of radiation. Cooling to liquid nitrogen temperature is needed to avoid excitation of electrons by thermal motion. These detectors do not cover the complete IR range because there is a minimum energy needed to excite an electron, corresponding to a long wavelength limit. Changing the composition can vary this limit, but extending the range reduces the sensitivity. The highest sensitivity is obtained with narrowband detectors, which have a limit of approximately 750 cm^{-1} , whereas wideband detectors reach 450 cm^{-1} , close to the limit for KBr optics. Scan rates are

Figure 17 The instrument response with a cooled detector showing nonlinearity.

not limited by the detector response, and indeed, the detector performance improves as the scan rate is increased. This allows data to be acquired at rates up to 100 scans per second in commercial instruments. The response of MCT detectors is inherently nonlinear (**Figure 17**). This restricts their use to low signal levels, typically less than 10% of the energy available. However, this is not a problem in applications where the signal level is restricted, such as microscopy. Because of the nonlinearity, the centerburst signal is compressed relative to the rest of the interferogram. After Fourier transformation, the primary consequence is an offset in transmission, so that totally absorbing bands do not appear at zero. The presence of nonlinearity can be detected by examining the single-beam signal in the region beyond the long wavelength limit of the detector. Any nonlinearity causes this signal to be nonzero. Various methods, both in electronics and in software, have been employed to minimize the effects of nonlinearity. None of these is entirely successful. For this reason, room-temperature detectors are preferred for quantitative measurements.

The combinations of components found in use for the three regions are summarized in **Table 1**.

Step-Scan Instruments

In most spectrometers, the path difference is scanned continuously, but in recent years, so-called step-scan instruments have become important for some research applications. In these instruments, the path difference is held constant at one point, whereas the interferogram signal is measured before being moved to the next point. The IR signal has to be modulated to match the frequency response of the detector. This is achieved by applying a small amplitude oscillation to the fixed mirror. In practice, a constant path difference can be maintained either by moving the two mirrors synchronously or by holding both stationary. Step-scan instruments can address a much wider range of dynamic measurements than continuously scanning systems because the signal modulation frequencies are not restricted by the velocity of the moving mirror (**Figure 18**).

The principal applications have been to very rapid kinetics and photoacoustic spectroscopy. The kinetic applications involve processes that are repeated for each

Table 1 Combinations of components found in use for mid-IR, near-IR, and far-IR regions

	Range (cm^{-1})	Source	Beam splitter	Detector
Mid IR	7000–400	Ceramic, wire, SiC	KBr, ZnSe	DTGS, LiTa, MCT, InSb
Near IR	15 000–4000	Tungsten halogen	CaF ₂ , quartz	DTGS, PbS, InGaAs, InSb
Far IR	400–20	Ceramic, wire, mercury arc	Mylar, wire grid, CsI ($> 200 \text{ cm}^{-1}$)	DTGS, Si

Figure 18 The difference between continuous and step scanning.

step of the path difference. The signal can be measured at time intervals limited only by the detector response and electronics. At each path difference, measurements are made at the same times after initiation of the process. The data are then reshuffled to create a series of interferograms in which each point was measured at the same time in the process. This approach has allowed FT-IR measurements to reach the nanosecond timescale. In photoacoustic spectroscopy, there are advantages because the modulation frequency is constant across the spectrum, making it feasible to measure the spectra of sub-surface layers.

Commercial Instruments

Present-day commercial laboratory spectrometers can be grouped into those intended for routine measurements and research instruments. In general, the routine instruments are designed to simplify operation, whereas research instruments aim to offer versatility. In virtually all cases, the instrument is controlled by a personal computer that handles an increasing amount of the digital signal processing in the system. There are also instruments with an integrated microscope that are used for very small samples or imaging. However, more commonly, microscopes are seen as accessories to normal spectrometers. Recent years have seen the introduction of a number of more compact and robust spectrometers for field or process applications.

A typical routine mid-IR spectrometer has KBr optics, with a best resolution of around 1 cm^{-1} , and a room-temperature DTGS detector. Noise levels below 0.1% T , peak to peak, can be achieved in a few seconds. To reduce the problem of fluctuating levels of atmospheric water vapor and carbon dioxide, much of the optical path is sealed and desiccated. The sample compartment will accommodate a variety of sampling accessories such as those for ATR (attenuated total reflection) and diffuse reflection. In most cases, the output from the interferometer can be directed through an external port, principally for coupling to an IR microscope. Other external accessories provide coupling to a gas chromatograph or thermogravimetric analyzer. These instruments often

have versions for NIR operation in which the source, beam splitter, and detector are different.

Research spectrometers are generally larger, permitting higher optical throughput and hence better signal-to-noise performance and higher resolution. There may be multiple external ports for the interferometer output so that several experiments can be installed simultaneously. The major components – source, beam splitter, and detector – are generally exchangeable, so that a wide spectral range can be covered. A common arrangement is to have alternative sources and detectors permanently installed and selectable by switching mirrors. Different ranges can then be selected simply by changing the beam splitter. For FIR operation, the beam splitters are generally Mylar films, which have a narrow range, or metal grids on a polymer substrate. Cooled silicon bolometers are the detectors of choice for high resolution and sensitivity. Some instruments have a vacuum version that removes the very strong water absorption in this region, allowing measurement out to 5 cm^{-1} . Although there have been relatively few reported applications, some spectrometers are also capable of measuring throughout the visible region.

The range of scan speeds is greater than in routine instruments. The higher speeds provide better performance with cooled detectors and allow kinetics measurements whilst the lower speeds are used with photoacoustic detectors. Digital signal processing is increasingly being used to facilitate experiments involving external modulation where two channels of information have to be acquired simultaneously. Examples include polarization modulation in reflection-absorption of species on metal surfaces and in measuring the dynamic dichroism associated with polymer stretching. Research instruments generally have both continuous-scanning and step-scan modes as discussed earlier.

In the 40 years since the introduction of the first commercial FT instrument, there have been great improvements in speed and sensitivity. Routine measurements using the common sampling techniques now take only seconds, so that further improvements in performance will bring little benefit. Future advances are more likely to be seen in the development in smaller and more

robust spectrometers. Although a number of instruments for field applications have appeared, it is probable that the simpler sampling possible with Raman spectrometers will make these the instruments of choice. There are areas where improved performance is desirable, such as the sensitivity of chromatographic interfaces and the spatial resolution of IR microscopes. However, recently, there has been little progress, and there is little prospect of significant advances in these areas. One area where advances can be expected is in imaging where there is real potential for medical diagnoses based on spectroscopy. The advent of step-scan spectrometers has led to great advances, but these have been in rather specialized applications. Thus, FT-IR instrumentation can be classified as mature. There is little prospect of any alternative methods of measuring IR spectra replacing FT instruments for most purposes. An exception is gas analysis where the development of mid-IR quantum cascade lasers operating at room temperature is likely to lead to novel analyzers.

Introduction

One of the strengths of IR spectroscopy as an analytical technique is the ability to obtain spectra from a very wide range of materials. However, in many cases some form of sample preparation is required in order to obtain a good quality spectrum. For direct transmission spectra, samples have to be no more than a few tens of micrometres thick. This means that reflection measurements are often needed if materials are to be measured in their original form. Fortunately, the choice of methods for obtaining spectra by reflection has expanded significantly in recent years. When neither transmission nor reflection spectra are satisfactory, spectra can generally be obtained by photoacoustic spectroscopy, although this is a relatively expensive option.

Modern spectrometers achieve very low noise levels and have a range of data processing options that can improve the appearance of spectra. However, these are not sufficient to generate a good spectrum from a sample that has not been prepared satisfactorily. In the context of this article, a good spectrum is considered as one that is suitable for comparison with reference data. This requires that the relative intensities, shapes and positions of both strong and weak bands should be observable. With modern spectrometers the intensities of bands at 1% transmission can be measured adequately for qualitative purposes, although for quantitative analysis it is wise to avoid bands at below 10% transmission. Although noise levels can be well below 0.1%, it should be remembered that the measurement of very weak bands is more likely to be hindered by interferences such as matrix impurities or instrument artefacts than by high-frequency noise.

Transmission Measurements

Liquids

Liquids are measured as thin films between IR-transmitting windows. The choice of window material depends on solubility, chemical compatibility and the range needed. The properties of common windows are listed in **Table 1**. For organic materials potassium bromide (KBr) is the most common choice. Zinc selenide has advantages for aqueous solutions because of the wide range, but the high refractive index leads to interference fringes that can be a problem for quantitative work, and calcium fluoride and barium fluoride therefore continue to be preferred. KBr and other alkali metal halide windows deteriorate with continued exposure to moist atmospheres and are easily scratched, but can be repolished fairly easily. Gloves should be worn to handle them to avoid fogging. The windows used for aqueous samples are more robust and are not generally repolished.

There are three main ways to measure liquids, in cells with spacers that may be fixed or demountable, or as a film directly between windows. In so-called sealed cells the spacer is a metal amalgam which provides a fixed pathlength. These are generally preferred for quantitative work. Demountable cells use a spacer made from metal foil or PTFE. The windows can be separated for cleaning or to change the pathlength. However, the pathlength generally changes slightly when the cell is reassembled, creating problems for quantitative work. When assembling demountable cells it is important to avoid dust particles on the spacer since these affect the spacing and can cause leaks. The pathlengths used for mid-IR measurements range from about 15 μm for aqueous samples to 500 μm or more for measuring components at low concentrations in weakly absorbing solvents. The pathlength of an empty cell is easily determined by measuring interference fringes. The thickness is equal to $(2 \times \text{fringe spacing})^{-1}$.

Care must be taken in filling short-pathlength cells because it is possible to generate enough internal pressure to damage the windows. For this reason it is a better practice to pull the liquid into the cell by attaching a reservoir to one port and a syringe to the other, than to push liquid into the cell from a syringe. The cell should be tilted for filling to avoid trapped bubbles that cause stray light. A demountable cell is shown in **Figure 1**.

Table 1 Properties of IR-transmitting materials

Material	Range (cm^{-1}) ^a	Refractive index	Properties
NaCl	> 600	1.52	Soluble in water and some alcohols, easily polished
KBr	> 400	1.54	As NaCl, hygroscopic
CsI	> 200	1.74	Soluble in water and some alcohols, very hygroscopic
CaF ₂	> 1100	1.40	Insoluble, attacked by NH_4^+ salts, robust
BaF ₂	> 750	1.45	As CaF ₂ , but sensitive to shock
ZnSe	> 500	2.43	Insoluble but attacked by acids and strong bases
ZnS	> 750	2.25	Insoluble, attacked by acids and strong oxidizing agents, good thermal shock resistance
Diamond	> 2200, < 1900	2.38	Highest chemical and mechanical resistance
KRS-5	> 250	2.38	Slightly soluble, attacked by bases, very soft, toxic
Sapphire	> 1600	1.62	Very hard, slightly soluble in acids and alkalis
Ge	> 600	4.01	Hard and inert, brittle
Si	> 650, < 450	3.42	Very hard and inert
AMTIR	> 725	2.5	Insoluble, attacked by bases, brittle
Polyethylene	< 625	1.5	Insoluble, swells in some organic solvents
Fused silica	> 2500	1.46	Insoluble
AgBr	> 300	2.30	Insoluble, attacked by acids and NH_4^+ salts, soft

^aThis is for windows. The longer pathlength in ATR elements generally reduces the range, e.g. to 650 cm^{-1} for ZnSe.

**Figure 1** Construction of a demountable cell for liquids.

Neat liquids can be measured by placing one drop on a window and putting a second window on top of this. The pathlength can be varied by applying pressure. This is very convenient for qualitative work, but cannot be used for very volatile materials.

For non-volatile liquids porous polymer films are a convenient alternative to conventional windows. These '3M cards' (**Figure 2**) are made of polyethylene or PTFE. The polyethylene films absorb in rather narrow regions and, except for the region near 3000 cm^{-1} , their absorptions can be removed by subtraction. The PTFE cards are useful for obtaining spectra in the CH stretching region around 3000 cm^{-1} .

Solids

The two most common forms of sample preparation for solids involve both grinding the material to a fine powder

**Figure 2** Spectra of 3M cards.

and dispersing it in a matrix. Scattering and reflection effects are reduced when the particle size is less than the wavelength of incident radiation, which in this case is a few micrometres. Surrounding the particles by a matrix with a similar refractive index further reduces the effects. Most samples can be ground either mechanically with a small vibrating mill or by hand with a pestle and mortar, the choice being a matter of personal preference. For manual grinding the amount of sample should be no more than around 20 mg. The sample should be ground until it is adhering to the sides of the mortar and has a glossy appearance. This process may take several minutes.

The ground material can be dispersed in a liquid to form a mull. The most commonly used liquid is mineral oil (Nujol), while a fluorinated hydrocarbon (Fluorolube) can be used to observe the 3000 cm^{-1} region (**Figure 3**). No more than one or two drops are needed to produce a paste that can be spread between windows. The

Figure 3 Spectra of mulling agents.

consistency of this paste is a compromise between the ease of spreading and the interference from the absorptions of the mulling agent.

Potassium bromide (KBr) is probably the most widely used matrix material, even though preparing a good KBr disc is time consuming and requires practice. Between 1 and 3 mg of ground material is mixed thoroughly with about 350 mg of ground KBr. The mixture is transferred to a die that has a barrel diameter of 13 mm. This is placed in a suitable press, evacuated and then pressed at around 12 000 psi for 1–2 min. Recrystallization of the KBr results in a clear glassy disc about 1 mm thick. Discs can be made with manual presses and without evacuation, but the best results are obtained with the more elaborate procedure.

Provided that the sample, the KBr and the disc are weighed, this technique can be used for quantitative work. It has the advantage that there are no matrix absorptions above 400 cm^{-1} , although adsorbed water in the KBr has to be avoided. Potential limitations are that the grinding and pressing can modify the crystalline form of the sample and that ion exchange can occur. To avoid ion exchange it is common to use potassium chloride for amine hydrochlorides. Caesium iodide is used for the region to 200 cm^{-1} while for far-IR measurements polyethylene is a suitable matrix. Grinding is the main issue in disc preparation (**Figure 4**). Inadequate grinding results in sloping baselines caused by light scattering and in asymmetric bands. The asymmetry, known as the Christiansen effect (**Figure 5**), results from refractive index differences.

Very few solid samples arrive in a suitable form for direct transmission measurement, the principal exception being polymer films. Unfortunately, interference fringes often distort the spectra. There are several techniques for eliminating interference fringes by reducing the surface reflections. The simplest are to abrade the surface or to sandwich the film between windows. Another possibility is to smear one surface with mineral oil, provided that this does not obscure important regions of the spectrum. Polymer samples that are too thick for direct measurements can often be pressed to a suitable thickness. Heated platens

Figure 4 Spectra from poorly (bottom) and well (top) ground discs.

Figure 5 Christiansen effect.

for making films of controlled thickness are available from accessory suppliers.

Simple compression cells with diamond windows have appeared more recently. Although they generate lower pressures than traditional diamond anvil cells, they can provide excellent spectra from a range of samples that are too thick for direct measurements.

Soluble materials can be prepared as cast films by evaporating them from solution on a suitable substrate such as a KBr window. An infrared lamp is a convenient means of warming the film to remove residual solvent. This approach is especially useful for those polymers that can be cast on to a glass block from which they can be removed for measurement without a support. A wide range of organic compounds can be prepared on the porous polymer substrates known as 3M cards. The best spectra are obtained when the compound forms an amorphous deposit. The spectra of crystalline samples may be distorted by scattering and reflection effects.

Gases

Measurements on gases require much longer pathlengths than those for condensed phases; 10 cm is usual for compounds at relatively high concentrations. For trace concentrations multiple reflection cells provide pathlengths of several metres in compact designs. Detection limits are well below 1 ppm for many compounds.

Internal Reflection Methods

In recent years, internal reflection methods have developed into perhaps the most versatile approach to obtaining IR spectra. Total internal reflection can occur at the interface between media with different refractive indices (**Figure 6**). If the angle of incidence exceeds a critical value, radiation cannot pass into the medium with the lower refractive index; instead, it is totally reflected. Although there is total reflection, an electric field, sometimes referred to as an evanescent wave (**Figure 7**), extends a short distance into the second medium. This distance is of the same order of magnitude as the wavelength. In an internal reflection measurement the radiation enters a high refractive index material and emerges after undergoing internal reflection. The high refractive index element is usually called the crystal, even though the material may be a glass. An absorbing sample placed on the surface of the crystal interacts with the electric field to generate a spectrum. This is called an attenuated total reflection or ATR spectrum. The band positions and

Figure 6 Total internal reflection at interface where $n_1 > n_2$.

shapes are slightly different from those in transmission spectra, but not enough to affect qualitative identification.

The penetration depth, d_p , of the light into the lower refractive index material is defined as the depth at which the field amplitude has fallen to $1/e$ of its value at the surface. For two materials with refractive indices n_1 and n_2 it is given by

$$d_p = \frac{\lambda_1}{2\pi(\sin^2 \alpha - n_{21}^2)^{1/2}}$$

where λ_1 is the wavelength in the higher refractive index material and is related to the incident wavelength λ by the expression $\lambda_1 = (\lambda/n_1)$, α is the angle of incidence and $n_{21} = n_2/n_1$.

The intensity of an ATR spectrum depends on the distance that the electric field extends into the sample and on the number of reflections. The most commonly used materials are zinc selenide and diamond, both with a refractive index of 2.3, and germanium, with a refractive index of 4.0. The higher refractive index reduces the distance that the electric field penetrates into the sample, giving a weaker spectrum. The depth of penetration is proportional to the wavelength, so that when ATR spectra are compared with transmission the intensities at longer wavelengths appear enhanced. For an ATR crystal with a refractive index of 2.2 and a 45° angle of incidence, the depth of penetration in a typical organic sample is about $4 \mu\text{m}$ at 1000 cm^{-1} .

Because ATR measurements are obtained from a thin surface layer, the spectra may not be representative of the bulk material. For example, spectra of polymer laminates such as packaging materials generally show only the surface layer. However, the spectra of emulsions and suspensions may be unrepresentative of the bulk material because of segregation at the surface.

There are two basic designs of ATR accessory in common use. These have replaced traditional designs in which a thin sample was clamped against the vertical face

Figure 7 Evanescent wave at an interface where $n_1 > n_2$.

Figure 8 Schematic of an HATR top plate for liquids.

of the crystal. In horizontal ATR (HATR) units the crystal is a parallel-sided plate, typically about 5 cm by 1 cm, with the upper surface exposed (**Figure 8**). Radiation traverses the length of the crystal, undergoing internal reflection at the upper and lower surfaces several times. The number of reflections at each surface is usually between five and ten, depending on the length and thickness of the crystal and the angle of incidence. Liquids are simply poured on to the crystal, which is recessed within a metal plate to retain the sample. Pastes and other semisolid samples are readily measured by spreading them on the crystal. HATR units are often used for quantitative work in preference to transmission cells because they are easier to clean and maintain.

When measuring solids by ATR, there is the problem of ensuring good optical contact between the sample and the crystal. The accessories have devices that clamp the sample to the crystal surface and apply pressure. This works well with elastomers and other deformable materials, and also with fine powders, but many solids give very weak spectra because the contact is confined to small areas. The effects of poor contact are greatest at shorter wavelengths where the depth of penetration is lowest.

The problem of contact has been overcome to a great extent by the introduction of accessories with very small crystals, typically about 2 mm across. The crystal is often diamond, which offers durability and chemical inertness. Germanium and silicon are lower cost alternatives. The accessories generally provide only a single reflection (**Figure 9**), but this is generally sufficient, given the very low noise levels of modern instruments. Because of the small area, much higher pressure can be generated with limited force. A much smaller area of contact is required than in conventional HATR units. As a result, spectra can be obtained from a wide variety of solid samples, even from minerals using systems designed for high pressures. Some accessories use a thin diamond element in combination with zinc selenide. This approach can provide multiple reflections, giving spectra equivalent to those from HATR accessories from very small sample volumes.

Figure 9 Schematic of a single-reflection ATR accessory.

Because of their versatility, accessories of this type are sometimes described as universal sampling devices. However, it must always be remembered that ATR only measures the surface of the sample.

The ATR technique is also employed with the unit inserted into bulk liquids, for example for process monitoring. The principle is exactly the same, the difference being that the form of the crystal is a prism so that radiation enters and leaves in the same direction. Radiation is coupled into the prism with light guides or optical fibres. There are also ATR probes in which the fibre itself forms the ATR element. The fibres are either chalcogenide glasses or mixed silver halides. One design of contact probe has a U-shaped section of exposed fibre that is pressed against the sample. This approach has been used for *in vivo* measurements of skin.

External Reflection Methods

Reflection measurements can be conveniently divided into surface or specular reflection and diffuse reflection. The reflection spectrum from the surface of a continuous solid, such as a large crystal or a block of polymer, does not resemble an absorption spectrum, being determined by the refractive index according to the Fresnel equations. However, it can be converted into an absorbance spectrum by a mathematical process called the Kramers–Kronig transform which is provided in the software from instrument suppliers. This is a common approach for obtaining spectra of single crystals and from polished surfaces of minerals. It is also very effective for carbon-filled polymers. Very simple accessories using two flat mirrors can be used to obtain reflection spectra from flat surfaces. The same accessories can be used to measure the spectra of coatings on metal surfaces such as protective or decorative polymer films on food and beverage cans. In this case what is measured is a transmission spectrum of the coating, the radiation having passed twice through the coating and having been reflected at the metal surface. This is sometimes called a transmittance measurement. Examples of the above are shown in **Figures 10** and **11**.

Diffuse reflection is seen when radiation penetrates below the surface before being scattered or reflected back from within the sample. Spectra of this kind have the

Figure 10 Reflection and reflection-absorption at surfaces.

Figure 11 Top, reflection spectrum of poly(methyl methacrylate); bottom, absorbance calculated by Kramers–Kronig transformation.

character of transmission spectra since there is absorption as the radiation travels inside the sample. Samples for diffuse reflection are generally powders (**Figure 12**). Accessories for this kind of measurement have to collect the light that emerges from the sample over a wide range of angles. Integrating spheres are little used because suitable large detectors are not available for the mid-IR region. Instead, commercial accessories focus the radiation on to a small region, typically 1–2 mm across, and collect over a wide but limited range of angles (**Figure 13**). The spectra obtained with these accessories represent a mixture of reflection from the surface and from within the sample. They can be used to measure pure surface reflection from samples that have no internal reflection or scattering.

In spectra obtained directly from powdered organic compounds, the stronger bands often appear flattened and are distorted by surface reflection. The diffuse reflection spectrum can be thought of as a transmission spectrum in which there is a range of different pathlengths. This results in enhancement of the relative intensities of the weaker bands. In general, the aim is to obtain a result that resembles a true transmission spectrum. The standard technique is to grind the sample to a fine powder, ideally to a particle size below 10 μm , and to mix this with a non-absorbing matrix such as finely ground KBr at a concentration of about 1%. The small particle size and dilution

Figure 12 Representation of diffuse reflection by a powder.

Figure 13 Optics of diffuse reflection accessory.

together ensure that absorption is weak for all pathlengths. This means that relative band intensities in transmission are similar for all contributing pathlengths and so are correct in the final spectrum. The presence of the non-absorbing matrix reduces reflection at the surfaces of the particles by better refractive index matching, and so minimizes the surface reflection component. Sample preparation is quicker than for a KBr disc. It is also gentler, making it less likely to induce changes in the crystalline form. However, it has proved difficult to achieve sufficiently consistent sample preparation to allow good quantitative measurements. Representative spectra of finely ground aspirin are shown in **Figure 14**.

Diffuse reflection spectra are often transformed to Kubelka–Munk units as defined below, just as spectra measured in transmission are converted to absorbance:

$$f(R_\infty) \propto (1 - R_\infty)^2 / R_\infty$$

where R_∞ is the ratio of the sample reflectance to that of a reference such as KBr. The reason is that under certain conditions the band intensities in these units are proportional to concentration. However, the necessary conditions are not met in typical mid-IR measurements, so there is little reason to prefer this presentation to the

Figure 14 Diffuse reflection spectra of finely ground aspirin. Top, diluted in KBr; bottom, neat.

Figure 15 Diffuse reflection spectra of aspirin in Kubelka–Munk and $\log(1/R)$ units.

alternative $\log(1/R)$, which is a direct equivalent of absorbance (**Figure 15**). It is worth noting that near-IR diffuse reflection spectra are used extensively for quantitative work, almost invariably using $\log(1/R)$ rather than Kubelka–Munk units.

Another way of presenting samples for diffuse reflection is as a thin film of fine particles. This also achieves the objective of ensuring weak absorptions. Samples can be taken from the surface of large objects by abrading them with silicon-carbide-coated paper. The spectrum of the material removed can be measured directly on the abrasive substrate. This method has proved ideal for painted surfaces and moulded plastic objects. It can be extended to very hard materials by using abrasive devices such as metal rods tipped with diamond powder. The main limitation to this technique is that abrading soft and rubbery materials generally does not produce particles that are small enough to give good spectra.

Photoacoustic Spectroscopy

Photoacoustic measurements are unique in that they depend directly on the energy absorbed by the sample, rather

Figure 16 The principle of a photoacoustic measurement.

than on what is transmitted or reflected (**Figure 16**). The sample is placed in a sealed chamber. When radiation is absorbed, it is converted into heat which can be detected as a change of pressure in the gas above the sample. This heat transfer process is sufficiently fast to follow the modulation of the radiation produced in an FT-IR spectrometer. The change in pressure is detected with a microphone. A spectrum is obtained by ratioing the detector signal to that generated with a totally absorbing material such as carbon black. As with ATR, the spectrum comes from a surface layer, but in this case the effective penetration can be more than $100\ \mu\text{m}$. This can result in total absorption for strong bands, so that relative intensities are distorted. The effective depth of penetration depends on the modulation frequency which varies with wavelength in rapid-scanning FT-IR spectrometers. In step-scan spectrometers the modulation frequency is constant for all wavelengths, so simplifying interpretation of the spectra. Some information about the depth distribution of different components can be obtained by varying the modulation frequency. However, depth profiling, measuring a concentration quantitatively as a function of depth, has not been achieved.

In practice, the main value of photoacoustic measurements has been in obtaining spectra from strongly absorbing samples such as carbon-filled polymers and for materials that cannot be ground to a fine powder or be prepared with a flat surface. Sample preparation is minimal, requiring only that the specimen is small enough to fit in the chamber. Commercial accessories can accommodate samples several millimetres across.

Microsampling

The approach to measuring small samples has been transformed by the widespread use of IR microscopes. The advantages over traditional beam condensers lie in much greater convenience and versatility, as well as in the ability to measure much smaller samples. The region

for measurement can be selected while a relatively large area of the sample is viewed. Spectra can be obtained from isolated samples that are only a few micrometres across. However, in extended samples diffraction limits spatial resolution to about 10 μm . Because of this, it is generally preferable to remove small inclusions from a matrix rather than to try to measure them *in situ*. One consequence of having very small samples is that it is often easy to compress them to a suitable thickness for transmission measurement. Compression cells are therefore more useful than they are with large samples. Sample preparation is greatly helped by having standard microscopy tools and a microtome available. Reflection measurements are more generally useful than they are with larger samples. Because of the small sample area and large collection angle, it is easier to find an area that gives a pure surface reflection spectrum. This can then be converted into an absorbance spectrum by the Kramers–Kronig transform.

Miscellaneous Techniques

Emission spectra can be obtained without any sample preparation, but they are of very limited use. If the sample is opaque, the information provided is identical with that in the reflection spectrum since the sum of transmission, reflection and emission at any wavelength adds up to one. The reflection spectra are usually measured more easily than emission. Emission is very useful to obtain spectra from thin coatings on uneven metal surfaces when diffuse reflection measurements would require a small sample.

Pyrolysis can provide qualitative information from intractable samples without requiring expensive accessories. The simplest approach is to heat the sample in the bottom of a long test-tube so that decomposition products condense at the top of the tube and can be measured by the usual methods. Commercial devices also allow gaseous products to be collected. There are collections of the spectra of decomposition products from polymers. The most sophisticated version of this method is to couple a gas cell in the

spectrometer to a thermogravimetric analyser and measure the products evolved at different temperatures.

Separation techniques are needed in order to identify individual components in mixtures. The most important of these is gas chromatography. To maximize sensitivity, the sample has to be confined to a small area. The usual approach is to pass the gas flow from the GC column through a light pipe ~ 1 mm in diameter and 10 cm long. This achieves detection limits of ~ 10 ng for strongly absorbing compounds. For higher sensitivity a more elaborate deposition method is available. The effluent from the column is directed on to a moving cold window where the peaks in the chromatogram can be condensed as a series of spots about 100 μm across. The detection limits are below 100 ng.

Coupling to liquid chromatography is much less successful because of the problem of eliminating the solvent and modifiers. In the most widely used system the eluate is deposited in a circular track on a rotating heated window which is subsequently transferred to the spectrometer. This is used especially in combination with size-exclusion chromatography.

Symbols

A	integrated absorbance
B_{if}	probability of an induced transition per unit time per unit radiation density
c	velocity of light
C	concentration
E_i	energy of <i>i</i> th mode
e_r	unit vector in the direction of the electric field vector of the radiation
F	quadratic force constant matrix
G	inverse kinetic energy matrix
h	Planck's constant
I	moment of inertia
I^v	intensity of radiation
k_B	Boltzmann's constant
l	pathlength
M	molecular mass
N_f	number of molecules in state <i>lf</i>
N_i	number of molecules in state <i>li</i>
Q	normal mode
ω	molecular angular velocity
ε₀	permittivity of free space
R	internal coordinate
v	vibrational quantum number
Γ	integrated absorption intensity
μ	dipole moment
ν	frequency
ρ	radiation density
ω	wavenumber

their relevance in spectroscopy the reader is referred to the Further reading section. In the event that a rigid point group is inappropriate, as for free rotors (e.g. CH₃BF₂), then the invariance of energy to certain distortions requires that permutation group theory be used. What we are seeking to explore with group theory is the invariance of energy and the consequences to certain transformations of the molecular configuration. In free rotors, by definition, the energy is unchanged by rotation about a bond. This then makes rigid group theory inappropriate.

For excitation of any single mode *i*, the energy, *E_i*, can be expressed as

$$\frac{E_i}{hc} = \omega_i \left(v + \frac{1}{2} \right) - \omega_i x_i \left(v + \frac{1}{2} \right)^2 + \omega_i y_i \left(v + \frac{1}{2} \right)^3 + \dots \quad [1]$$

where *v* is the vibrational quantum number and *ω*, the wavenumber, is *v/c*. Restricting the discussion initially to a harmonic oscillator with no molecular rotation, we can then examine the conditions required for vibrations to be excited through interaction with electromagnetic radiation. For absorption the following conditions must be satisfied:

The photon energy, *hν_i*, must be equal to the change in vibrational energy. We should qualify this by giving due allowance for the Doppler effect. In a low-density gas the spread of molecular velocities relative to the probing beam leads to a natural line width, *Δν*, at a temperature *T* of

$$\Delta\nu = \frac{v_i}{c} \left(\frac{2k_B T \ln 2}{M} \right)^{\frac{1}{2}}$$

Factors Which Control Absorption

Absorption in the infrared region arises predominantly from excitation of molecular vibrations. For *N* atoms there are 3*N*–6 vibrational degrees of freedom (3*N*–5 for a linear molecule), which is equivalent to stating that all vibrational distortions can be described as the sum of 3*N*–6 ‘fundamental’ vibrational modes. Where any symmetry exists in a molecule, the vibrations will reflect that symmetry in that the vibrational wavefunctions will be symmetric or antisymmetric with respect to any simple symmetry element. This statement has to be modified slightly for situations where degeneracy of rotations occurs. For a detailed discussion of groups and

where *M* is the relative molecular mass. Such widths are very small and relevant only when probing fine structure. Thus, for methane at room temperature and for a band at *ω* = *v_i*/*c* = 1500 cm^{–1} then *Δω* = 0.003 cm^{–1}. By using molecular beams moving at right-angles to the probing beam resolutions substantially better than this are attainable. Other techniques exist for exploring intrinsic line widths which are less than the Doppler width. These include two, or more, photon excitation and saturation spectroscopy.

Interaction of electromagnetic radiation and matter can only occur through electric and magnetic fields. For vibrational spectroscopy the electric field interaction is by

far the greater. In classical terms there must be a change in dipole moment for the vibration to be excited. Thus for stretching of the bond of a homonuclear diatomic no absorption at the vibrational frequency occurs. In general, the absorption is proportional to the square of the dipole change. In terms of group theory only those vibrations which form representations of the same classes as the electric dipole vector (or simple translations) can be excited by electromagnetic radiation (EMR). Thus, for CF_3CF_3 (D_{3h} symmetry), only vibrations of the A_1'' and E' species can absorb electromagnetic energy of the appropriate frequency since a dipole vector forms such representations. We must note that it is unnecessary for an electric dipole to exist in the equilibrium configuration.

According to quantum mechanics, the probability of an induced transition per unit time per unit radiation density between states $|i\rangle$ and $|f\rangle$ is given by Fermi's 'Golden Rule':

$$B_{if} = B_{fi} = 2\pi^2/b^2\epsilon_0|\langle f|\hat{e}_r \cdot \mu|i\rangle|^2\delta(v - v_f + v_i) \quad [2]$$

where ϵ_0 is the permittivity of free space, $\hat{e}_r$ is a unit vector in the direction of the electric field vector of the radiation and $\delta()$ is the Kronecker delta, which takes the value zero unless its argument is zero, in which case it has a value of unity. In the above equation the Kronecker delta requires that the radiation frequency is exactly equal to the difference in energies of the initial and final states divided by Planck's constant.

For an ensemble of randomly oriented molecules, the power absorption is given by

$$dI_v = (N_i B_{if} - N_f B_{fi})\rho_v \quad [3]$$

where N_i is the number of molecules in state $|i\rangle$ and ρ_v is the radiation density. Defining the intensity over the k th band as

$$\Gamma_k = \frac{1}{Cl} \oint \ln \frac{I_0^v}{I^v} \frac{dv}{v} \quad [4]$$

and assuming harmonic oscillator wavefunctions, then eqns [2], [3] and [4] yield

$$\Gamma_k = \frac{N\pi}{3v_k} \left(\frac{\partial \mu}{\partial Q_k} \right)^2$$

where C is the concentration of the absorbing species, l is the pathlength, I^v and I_0^v are the intensities of radiation at the frequency v with and without the sample absorption and $\partial \mu / \partial Q_k$ is the dipole change with respect to the vibrational motion in normal, or fundamental, mode k . v_k is the fundamental transition frequency. The definition of band intensity in eqn [4] differs from the usual integral (the integrated absorbance, A) in the presence of v in the denominator, but is much more satisfactory in relation to theory and to isotopic intensity sum rules. Since the band

widths are generally much smaller than the frequency band centre, the integrated absorbance, A , is related to Γ by $A \approx \Gamma v$.

The dipole moment can be written as a Taylor series expansion in the vibrational motion Q :

$$\mu = \mu_0 + \frac{\partial \mu}{\partial Q} Q + \frac{1}{2} \frac{\partial^2 \mu}{\partial^2 Q} Q^2 + \text{higher terms}$$

For a harmonic oscillator, quantum theory requires that the transition integral $\langle f|Q|i\rangle$ disappears unless the vibrational quantum numbers v_i and v_f are related by $v_i - v_f = 0$ or ± 1 . This requires that overtones are forbidden if only the linear term in Q exists. It is known, however, that the vibrational spectrum contains weak features due to overtones and combination bands in which two quantum numbers change simultaneously. These occur because the dipole expansion in general has finite terms quadratic in the deformation and because true wavefunctions are nonharmonic. Occasionally combination bands appear with considerable strength due to mixing with a nearby fundamental transition of the same symmetry (Fermi resonance). Interaction leads to mutual repulsion of the mixed energy states. In the event that the combination transition has zero or much less intensity than the fundamental, then the unperturbed fundamental transition can be estimated as the intensity weighted mean of the two bands. A classical example of Fermi resonance is seen in the infrared spectrum of CCl_4 . The very strong doublet at $768/797 \text{ cm}^{-1}$ is due to the triply degenerate CCl stretch interacting with the combination state $v_1 + v_4$ ($305 + 458 \text{ cm}^{-1}$).

There is considerable interest in the factors that determine the dipole derivative. The stretching of a highly polar bond, such as C–F, might well be expected to lead to a large dipole change. In practice, the dipole change is much greater than would be expected for the charges on the atoms in their equilibrium positions. Charge flows as the nuclei move, in this case towards the situation where the fluorine atom carries a complete extra electron. In certain cases where a *trans* lone pair of electrons exist, such as for the hydrogen atom in the aldehyde unit, extension of the bond results in a flow of electrons from the lone pair into an antibonding orbital of the C–H bond, thereby greatly enhancing the dipole change. This is the same phenomenon that is responsible for bond weakening in such cases. In bending motions, nonbonding interactions, as well as rehybridization of the electrons at the nonterminal atom, cause substantial deviations from the dipole change expected from the equilibrium charge distribution. This explains the remarkably high spectral intensity associated with movement of a hydrogen atom from the plane of benzene or ethene derivatives. As the electrons rehybridize around the carbon (moving from sp^2 towards sp^3), so electrons build up on the opposite

side of the skeletal plane to the hydrogen, thereby enhancing its positive charge.

Many studies have been made of the absorption intensities associated with bands arising from group vibrations. It is recognized that the transition moments are far more sensitive to neighbouring group effects than are the frequencies themselves, and intensities are not particularly useful in evaluating the concentration of functional groups. However, some qualification of this statement is required in view of the widespread application of principal factor (or principal component) analysis (PFA) in industrial spectroscopy. This has been mainly used with near-infrared spectra, but this is probably more to do with ease of generating suitable spectra than to fundamental limitations. The application to the mid-infrared spectra of coals is an excellent example. The relevance to group intensities is that PFA is a statistical technique of fitting data to a progressively increasing number of unknown components until the fit reaches an acceptable level. As such it requires the data to consist of a finite number of linearly additive components. The application to very complex mixtures such as coals, wheat and petroleum, both refined and unrefined, strongly suggests additivity is much better than used to be believed. This has been rationalized by demonstrating that group spectra are characteristic provided that the neighbouring groups are the same.

Band Shapes in Liquids

In low-density vapours an absorption band consists of lines arising from a large number of transitions arising from rovibrational transitions, perhaps from excited vibrational states as well as the ground state. In high-density fluid states the interaction between different molecules will affect the spectrum by causing perturbations of the rovibrational energy states and by reducing the lifetimes of the excited states through energy transfer processes. The individual transitions initially broaden and then merge into a smooth band contour. It is sometimes stated that the rotational transitions are suppressed, but this cannot be so. The equipartition theorem states that energy must be equally distributed between each degree of freedom, and this must extend to the condensed state. It has been demonstrated that the contours still contain the rotational contribution. Thus for a diatomic molecule of moment of inertia I , the integrated second moment of the intensity (Γ as defined in eqn [4]) about the vibrational band centre, divided by the integrated intensity itself, is, apart from a vibrational relaxation contribution, $k_B T/I_X$, where I_X is the moment of inertia. This is the same for vapour and for liquid. It is simply the relaxation of the excited states that has changed. There is a vibrational contribution to the width (see below). It is possible in certain situations to separate these contributions using Raman spectroscopic

methods. If we designate the transition dipole moment at a time t of a given transition as $\mu(t)$ then its development as a function of the time lapse $t = t'' - t'$ is related to the Fourier transform about the band centre of the intensity as

$$C(t'' - t') = \langle \mu(t'') \cdot \mu(t') \rangle = \langle \mu(0) \cdot \mu(t'' - t') \rangle \\ = \int_{-\infty}^{+\infty} \Gamma(\nu_0 + \Delta\nu) \exp(i2\pi\Delta\nu t) d\nu$$

The brackets $\langle \rangle$ designate an ensemble average and, since the transition dipole is a vector, this transform yields the ensemble time decay of the transition dipole moment from an arbitrary time of origin. The time scale of the decay will be of the order of the inverse of the band width. Thus for a band of half-band width 10 cm^{-1} the half-life of the decay will be $\sim 1/(3 \times 10^{10} \times 10) \approx 3 \times 10^{-12} \text{ s}$. If we discount vibrational relaxation and consider the transition moment as being fixed to the molecule, then the correlation function $\langle \mu(0) \cdot \mu(t' - t'') \rangle$ will describe the rotation of the molecule as defined by the transition dipole axis. In the condensed state after an initial period in which the motion is governed by the rotational energy, then decay becomes exponential due to collisional processes. In the vapour the dipole correlation shows a minimum, perhaps becoming negative, in a period after which most molecules are facing in the opposite direction to that in

Figure 1 The dipole autocorrelation function of the ν_{11} band of benzene. The top line is the dipole correlation function for benzene dissolved in cyclohexane and the bottom line is that for benzene vapour. Hill IR and Steele D, unpublished work.

which they started (see **Figure 1**). As in magnetic resonance, the decay time will consist of isotropic and anisotropic contributions. In a fluid the transition dipole will also decay by transfer of energy between molecules and by multi-body collision deactivation of the vibration. These are responsible for the isotropic component. Owing to the very short time-scale of these processes, separation of the relaxation mechanisms is generally impossible. However, some progress has been made with laser optical nutation experiments and with Raman studies.

Calculation of Vibrational Spectra

Although energetic aspects of vibrational spectroscopy, such as zero point energy and crystal lattice energies, are strictly quantum phenomena, much can be achieved by classical-type calculations based on inter-atomic potential functions. Assuming that the potential energy for deformation about an equilibrium configuration is strictly quadratic in deformations then the vibrational frequencies are given as the eigenvalues of the matrix product $\mathbf{GF}$ where $\mathbf{F}$ is the matrix of quadratic force constants and $\mathbf{G}$ (so-called inverse kinetic energy matrix) is such that

$$G_{ij} = \sum_k \frac{\partial R_i}{\partial \xi_k} \frac{\partial R_j}{\partial \xi_k} \frac{1}{m_k} \quad \xi = x, y, z$$

where R represents an internal coordinate system of the molecule, usually chosen from bond stretches, angle bends and bond torsions. The sum is over all atoms. The methodology of carrying out these classical calculations are well documented. One of the principal advantages of such calculations is that the eigen-vectors of $\mathbf{GF}$ yield the nature of the molecular vibration.

Up to this point we have assumed harmonic oscillations. In reality we cannot ignore the impact of cubic and higher terms in eqn [1]. For a change in quantum number of Δv then from eqn [1] we have for a transition $|0\rangle \rightarrow |v\rangle$

$$\frac{\Delta E}{hc} = \omega_i \Delta v - \omega_i x_i (2v + 1) \Delta v + \text{higher terms}$$

A fundamental transition ($v=0 \rightarrow 1$) then has a wave-number of $\omega_i - 2\omega_i x_i$. The anharmonicity constant x is much less than 1. For the C–H vibrations it is relatively large because of the considerable amplitude of vibration, and it has a value of 0.021. This means that for a transition seen at 3000 cm^{-1} the fundamental frequency is at 3126 cm^{-1} . The first overtone would be expected at $2\omega_i - 6\omega_i x_i = 5874 \text{ cm}^{-1}$. In fact the C–H stretching overtone and combination frequencies deviate from these expectations. The cause of this lies in the large amplitudes of motion which result in a breakdown of local symmetry. A methylene group in an environment which

Figure 2 Relative energies in the local mode model of ground, fundamental, first harmonic and combination states for a system with two degenerate vibrators. A fundamental harmonic wavenumber of 3100 cm^{-1} and a vibrational anharmonicity of $\omega x = 60 \text{ cm}^{-1}$ have been assumed. ZPE represents the zero point energy.

conserves the equivalence of the two bonds will have vibrations which are symmetric and antisymmetric with respect to the bonds, and in the limit of small amplitude vibrations point group symmetry applies. As the amplitudes of all the vibrations increase, so the symmetry breaks down and the bonds tend towards independent oscillators. In this event the theoretical model needed becomes that of the local mode. Application of eqn [1] shows that the separation of states in which one of two equivalent bonds is doubly excited and that in which both bonds are singly excited is $2x_i \omega_i$. The higher transition will be at twice the observed fundamental frequency (see **Figure 2**).

Quantum Theoretical Calculations of Spectra

Applied quantum theory has reached the stage where infrared and Raman spectra can be predicted to a very useful degree of accuracy for molecules of fairly substantial size. The ability to programme the calculations so that force constants and dipole gradients are calculated analytically from the wavefunctions is one of the features which has greatly enhanced these computations. The calculations as routinely performed are of the harmonic wavenumbers and the band intensities. At the Hartree–Fock level the wavenumbers are too high when compared with experiment owing to the harmonic approximation, but also due to lack of electron correlation and the restriction of electron pairing. The latter leads to

dissociation to states in which electron pairing is still present, and these are generally of much higher energy. Very good results are obtained by simply multiplying the wavenumbers (frequencies) by a scaling factor. Improved results are generated by scaling the force constants, keeping one factor for C–H stretching, another for the C–H bending constants, etc. Improved results, with scaling constants nearer to unity, are obtained with perturbation calculations of the electron correlation correction (Möller–Plesset theory). Density functional theory (DFT) now permits very good frequencies to be obtained in times which are close to the Hartree–Fock times. Both Raman and infrared intensities are much more difficult to compute. This is not surprising when it is seen that dipole moments are extremely sensitive to the basis sets. Although these calculations have led to much improved force fields and computed spectra, which can be employed in interpreting experimentally observed spectra (typically with the inclusion of ‘correction factors’) it must be said that some difficulties still exist.

Vibration Rotation Spectra

When a vibrational quantum state changes, other quantum states of lower energy will also generally change. Thus, for a heteronuclear diatomic molecule the $|0\rangle$ to $|1\rangle$ transition is accompanied by a change in rotational quantum number of ± 1 leading to the well-known P and R branches. For polyatomic molecules the selection rules required so as to allow the nondisappearance of the transition integral are more complex, and for details the reader is referred to a specialist text. In the situation where individual rovibrational transitions cannot be resolved in an asymmetric top, then the overall contour can be related to the direction of the transition moment with respect to the inertial axes and to the moments themselves. Thus transitions in which the dipole change occurs along the direction of greatest moment of inertia are characterized by a strong Q branch (type C bands), corresponding to no change in the rotational quantum number change (see **Figure 3**).

The contours have been calculated as a function of the moments of inertia and presented in easily used figures. With laser and high-resolution Fourier instruments, an increasing amount of detail of rovibrational information is becoming available. Here we shall refer to a few general points.

The parameters of fitting include the moments of inertia. Even with small molecules and isotopically substituted molecules it is very difficult to generate accurate molecular geometries. The inertial constants refer to the ground and vibrationally excited states, but even in the ground state at the absolute zero of temperature each quantum state has a half quantum of energy (zero point

energy, see **Figure 2**). The average of the root mean square bond length during a vibration differs significantly from the equilibrium bond length. *Ab initio* calculations, such as referred to in the previous section, may be used to estimate the necessary corrections.

One feature unique to vibration rotation interaction is due to Coriolis interaction. There is a component of force on a moving particle due to rotation about a perpendicular axis equal to

$$\omega \otimes (\omega \otimes m_i r_i)$$

where $\otimes$ represents the vector product operator, ω is the molecular angular velocity and m_i and r_i are the mass and coordinate of the i th particle. Such coupling leads to interaction between two states, the product of whose symmetry representations belongs to the same species as a molecular rotation. For degenerate vibrations, this can be a first-order effect and has a dramatic impact on the overall vibrational rotational contour. The same phenomenon, of course, controls the contrary direction of rotation of air masses in the northern and southern hemispheres.

Introduction

Isotopes of an element contain the same number of protons but different numbers of neutrons. Whereas the former means that isotopically different compounds undergo the same reactions, the latter means that they differ in mass (e.g. ^{12}C and ^{13}C are 12 and 13 atomic mass units, respectively). As a result of their different masses, isotopes of an element participate in chemical, biological and physical processes at different rates. Hence, the isotope composition of the element in a given compound depends on the history and origins of the sample. Isotope abundance data can provide information concerning the source of a material or processes responsible for its synthesis and conversion. Variations in the isotope abundance ratios of many elements of biogeochemical importance are subtle, but significant. To resolve these differences, isotope ratio mass spectrometers must accurately measure variations of 20 to 50 parts per million. In the case of carbon, the average $^{13}\text{C}/^{12}\text{C}$ isotope abundance ratio of 0.011 200 ranges over $\pm 0.000\,450$ with biogeochemically important variations of $\pm 0.000\,000\,5$. Such requirements have resulted in a branch of mass spectrometry that has developed its own specialized instrumentation and analytical methods.

Isotope ratio studies are employed in a variety of multidisciplinary research projects encompassing chemistry, physics, biology, medicine, geology, archaeology and environmental technology. This article will describe mechanisms responsible for isotope abundance variations, the essential components of the isotope ratio mass spectrometer (with particular reference to electron impact ionization) and isotope abundance variations of H, C, N, O and S. Finally, the development of recent isotope ratio monitoring techniques to extract isotope information from transient signals is presented.

Natural Isotope Ratio Variations

To understand how mass differences give rise to isotope abundance variations, it is useful to consider chemical bonds as harmonic oscillators with fundamental vibrational frequencies inversely proportional to the square root of the molecular masses. The zero point energy of a molecule is defined as the finite energy (above $h\nu$ where h is Planck's constant and ν is the frequency of the oscillation) possessed by that molecule at 0 K. Isotope substitution changes the mass of the molecule and results in a shift in the zero point energy. A molecule containing a lighter isotope of an element will have a higher vibrational frequency and hence higher zero point energy compared to the molecule with the heavier isotope. The bonds in the molecule with the higher zero point energy are more easily broken. For all elements except hydrogen, the vibrational terms have the largest isotope effect. The magnitudes of these effects are proportional to the relative mass difference between the isotopic species.

Processes that result in isotope ratio variations can be divided into three general categories: (1) isotope exchange reactions such that isotopes of an element are redistributed among different molecules or different phases of the same molecule at thermodynamic equilibrium; (2) unidirectional processes where the reaction rates of chemical or physical reactions of isotopic species differ; and (3) radiogenic decay.

Equilibrium Isotope Effects

Equilibrium isotope exchanges involve the redistribution of an element's isotopes among different chemical compounds

or different phases of a molecule. While chemical equilibrium is necessary in order to attain isotopic equilibrium, isotope exchange will occur without any net change in the distribution of the chemical species in the system. Generally, the heavier isotope is favoured in the molecule that has the lowest zero point energy or the more condensed phase. The equilibrium constant of the isotope exchange reaction is related to the partition function ratios of the products and reactants. Partition functions control the distribution of internal energies within molecules. It is possible to calculate reduced partition function ratios and hence equilibrium constants for simple gaseous molecules (and to some extent condensed phases) based on spectroscopic and thermodynamic data. The dependence of the equilibrium constant on temperature is such that at higher temperatures the extent of isotope fractionation decreases.

The relationship between the isotope abundance ratios of the different species in the reaction is expressed as the fractionation factor ' α '. For example, consider the oxygen isotope exchange of H_2O between condensed and vapour phases:

The corresponding isotope fractionation factor α is 1.0092 at 25°C , i.e. the liquid phase is enriched in ^{18}O over the gaseous phase by 0.92 percent (eqn [1]):

$$\alpha_{\text{liquid-vapour}} = \frac{(^{18}\text{O}/^{16}\text{O})_{\text{liquid}}}{(^{18}\text{O}/^{16}\text{O})_{\text{vapour}}} = 1.0092 \quad [1]$$

Kinetic Isotope Effects

Kinetic isotope effects are observed in unidirectional processes (such as diffusion, evaporation, and bacterial conversions) where the reaction rate depends on the masses of the reacting molecules. Given the same amount of kinetic energy, molecules of lighter mass m_1 will react at a rate $\sqrt{(m_2/m_1)}$ faster than the heavier molecules of mass m_2 .

Biochemical reaction pathways are often dependent on the mass of an element at a particular position in a molecule. The result mostly is to favour the lighter isotopic species in the formation of the product. Often, exact information about the intermediate activated complex between reactants and products is not available. This makes calculation of rate constants and hence isotope fractionations from first principles difficult.

Radiogenic Isotopes

The transmutation of elements due to radioactive decay is another important cause of isotope abundance variations. Over time, the numbers of radioactive parent isotopes will decrease as they decay into the daughter products. The abundance determination of radiogenic

daughter isotopes is applied extensively for age determinations of geological and organic materials. The ages of minerals and rocks (t) can be calculated from the measurement of the number of daughter nuclides formed in a mineral that decayed under closed conditions (D^*) and the parent atoms (N) where the half-life of the parent (probability of a decay, λ) is known (eqn [2]).

$$D^* = N[\exp(\lambda t) - 1] \quad [2]$$

Successful age determinations are possible providing (1) the rock or mineral has remained closed and changes in the numbers of parent and daughter atoms are due to nuclear decay only; (2) the decay constant is known accurately; (3) the number of daughter nuclides originally present (at time $t=0$) is known; and (4) the numbers of daughter and parent atoms can be measured accurately.

Isotope Ratio Mass Spectrometer

The majority of isotope abundance determinations are performed using magnetic sector mass spectrometers based on a design from Alfred Nier dating back to the 1940s. The isotope ratio mass spectrometer consists of an ion source, magnetic sector and Faraday cup ion detector(s) (Figure 1). The source is responsible for the production of ions from either solid or gaseous material. The magnetic sector separates ions according to their mass to charge ratio and brings them into focus at the collector. The detector records and converts the charge of the ions into (computer readable) electrical signals. Neutral species are removed from the interior of the mass spectrometer (maintained at less than 10^{-8} mbar or 10^{-6} Pa) to minimize the number of collisions between ions and residual molecules in the ionization and analyser regions. These interactions would otherwise cause the ions to lose variable amounts of kinetic energy, resulting in a defocused ion beam.

Isotope ratio mass spectrometers tend to be of low resolution (~ 100 , 10% valley) to resolve the isotopomers in the simple gases introduced (i.e. in the case of CO_2 gas; $^{12}\text{C}^{16}\text{O}_2^+$, $^{13}\text{C}^{16}\text{O}_2^+$ and $^{12}\text{C}^{16}\text{O}^{18}\text{O}^+$ have masses 44, 45 and 46). The mass spectrometer provides high precision isotope abundance data, typically of the order of 0.001%. This is achieved by optimizing the number of ions collected at the detector to improve the counting statistics.

Magnetic Sector

The task of the ion optics of the mass spectrometer (of which the magnetic sector is the critical component) is to bring all of the ions produced at the ion source into focus at the collector. Ions formed in the source are collimated and accelerated through an electric potential difference (V) from 2000 to 10 000 V, depending on instrument type.

Figure 1 Typical mass spectrometer and inlet system for isotopic comparison of an unknown sample with a reference gas of precisely known isotopic composition. Clean gases are needed for such systems.

Figure 2 Flat-topped peaks ensure that small fluctuations in the magnet current or high voltage regulation do not hamper precision. For clarity, the peaks are recorded with different sensitivity factors (1:100:300 for 44, 45 and 46).

The accelerated ions enter the magnetic field and are separated along radial paths dependent on their charge to mass ratio and kinetic energy. The radius (r) of the path traced by an ion while in the magnetic field is related to its mass (M), charge (q), the potential of the source (V), and the magnetic field flux density (B) according to eqn [3]:

$$r = \sqrt{\frac{2MV}{qB^2}} \quad [3]$$

It is possible to change either the accelerating potential of the source or the magnetic field strength to bring an ion of a given mass into focus at the collector. A unique feature of the magnetic sector isotope ratio mass spectrometer is the trapezoidal peak shape produced by the selection of ion source (entrance) and collector (exit) slit widths (Figure 2). As the ion beam is scanned across the exit slit of the mass spectrometer, the ion current increases until the entire width of the ion image is contained inside the collector. The resulting flat-top peak ensures that the measured ion current does not change if

there are small fluctuations in the accelerating potential (V) and/or magnetic flux density (B).

Faraday Cup Detectors

The ion currents realized with most applications are of the order of 10^{-9} A for the major (most abundant) isotopic species and can be measured by a Faraday cup type detectors (Figure 3). The Faraday cup is connected to ground via a high ohmic resistor (10^8 to 10^{12} Ω). The incident ions produce a current (I) resulting in a voltage drop (V) across the resistor (R) proportional to the ion current incident at the collector by Ohm's law ($V = IR$). Either voltage to frequency converters or analog to digital converters digitize the voltage for computer-assisted processing of the data.

The accurate Faraday cup detector must neutralize the incoming singly charged particle with exactly one electron. However, due to the energy of the ion (2 to 10 keV), the surface of the detector is sputtered and secondary electrons and ions are ejected. These must be suppressed to prevent a false measurement of the ion current. Therefore, Faraday cup detectors are mostly thin, deep boxes with graphite surfaces and an electric field (~ 100 V) at their entrance to force secondary electrons back into the cup. The noise of the detector system can be no greater than 1.5×10^{-16} A or 1000 ions per second in order to measure the ratio of $^1\text{H}^2\text{H}$ to $^1\text{H}_2$ with a precision of 0.01% (where a sample of ocean water contains about 156 ppm H and the $^1\text{H}_2^+$ signal is 5×10^{-9} A).

As suggested by the name isotope *ratio* mass spectrometry, more than one ion current is measured in order to determine isotope abundance ratios. Most modern isotope ratio mass spectrometers have from 3 to 8 collectors carefully positioned along the focal plane of the instrument to measure several isotopic ion currents

Figure 3 Schematic layout of a Faraday cup assembly. The cups are deep and have secondary electron suppression in order to precisely record one charge per incoming singly charged ion. Different resistor values are used depending on the ion current in question.

simultaneously, typically a few mass units apart. This configuration is known as simultaneous collection and has several advantages over designs employing a single detector. Since multiple detectors are measuring the different isotopic ion currents at the same time, any changes in the total ion current affect the signal in all detectors. Fluctuations in the production of ions by the ion source effectively cancel and the stability of the ion current is not a limiting factor.

Ion Source

Two ion production methods are employed for isotope abundance ratios. Thermal ionization is best suited for the analysis of nanogram quantities of metals. Electron impact is suitable for the measurement of gaseous samples and is the most widely used ionization process.

Thermal ionization

Thermal ionization sources produce ions by heating sample-coated metallic filaments. Samples in solution are first deposited as microlitre drops on the filaments and dried at low temperatures forming thin salt or oxide layers (**Figure 4**). The prepared filament is transferred into the mass spectrometer source, the source is evacuated, and the filament is then heated to temperatures ranging from 800 to 2000 °C. The probability of forming an ion in thermal equilibrium with the surface of the hot metal filament depends on the temperature (T), work function of the filament (W), and the ionization potential associated with the production of a given ion species (IP). This is described by the Langmuir–Saha equation as the relative number of ionized particles (N^+) to neutral species (N^0) evaporated from the filament (eqn [4])

$$\frac{N^+}{N^0} \propto \exp \left[\frac{(W - IP)}{kT} \right] \quad [4]$$

Figure 4 Deposition of sample on an Re filament for thermal ionization analysis.

Typically, a filament material is chosen such that the work function of the metal is higher than the ionization potential of the sample. The filament is just heated to temperatures that allow efficient ionization without melting the metal.

Using similar techniques, it is also possible to produce and analyse negative ions. This method has the advantage of allowing a number of elements with high ionization potentials to be more easily ionized as negative atomic or oxide species (i.e. B, Se and Re). Again, the number of ions relative to the number of neutral species produced can be described by the Langmuir–Saha equation. In this instance, the relative number of negative ions (N^-) produced depends on the electron affinity of the sample (EA) as well as the filament's temperature (T) and work function (W) (eqn [5]):

$$\frac{N^-}{N^0} \propto \exp \left[\frac{(EA - W)}{kT} \right] \quad [5]$$

Mass-dependent fractionation processes that occur during the ionization process limit the ultimate accuracy and precision of isotope ratio measurements. As the sample is heated and ions are formed, the lighter isotopic species will evolve from the filament at a faster rate. The remaining (unionized) sample becomes relatively more enriched in the heavier isotopes and no longer has a representative isotope composition. Corrections to this fractionation are based on empirical calculations according to exponential or Rayleigh distillation models.

Principal applications of thermal ionization mass spectrometry (TIMS) are in the earth sciences to measure radiogenic isotopes for age determinations (i.e. U–Pb,

Pb-Pb, Rb-Sr, Re-Os, Nd-Sm), absolute isotope abundance measurements, tracing of Pb and other metals in the environment, and isotope dilution mass spectrometry. The high efficiency of the ion source for many elements (i.e. 1 ion collected for every 200 rubidium atoms on the filament) allows very small samples (10^{-9} to 10^{-12} g) to be analysed.

Electron impact

Electron impact sources ionize gases by collisions with transverse electron beams of up to 1 mA current and 100 eV energy (Figure 5). The mostly singly charged ions produced are extracted from the ionization region by an applied electric field that further serves to collimate and accelerate the ions. The resulting ion current depends on the amount of sample gas inside the ion source. The influx of the sample gas into the ion source is of the order of 10^{-12} mol s $^{-1}$ under viscous flow conditions. The electron impact ion source will result in 1 ion being collected for every 1000 to 10 000 molecules introduced, depending upon the sensitivity of the ion source and the focusing properties of the mass spectrometer. Collisions in the ion source between ions and neutral species can lead to a nonlinear dependence of the ion current ratios with the source pressure. To prevent this, ions must be extracted immediately after formation. For isotope abundance measurements, simple gases (e.g. CO $_2$, N $_2$, H $_2$, SO $_2$, CO) are prepared from raw materials being careful to preserve the isotope composition of the sample.

Figure 5 Schematic diagram of an electron impact ion source for the ionization of gaseous samples. The whole ion source is closed, leaving only small holes for the electrons to enter and the ions to exit. This ensures the highest sensitivity by having the gas molecules pass through the ionization region several times before being pumped away.

Inlet systems: the changeover concept Mass spectrometers do not measure isotope abundance ratios accurately due to inherent biases caused by the ion optical design, ion current detectors and electronics, and method of sample preparation. In practice, to correct for machine bias, the measured ion current ratios of the sample are compared to those from a reference gas (of known isotopic composition) analysed under identical operating conditions. This can be achieved using a *dual inlet* system with two stainless steel variable volumes (1 to 100 mL) for reference and sample gases (Figure 1). The volume of these reservoirs is adjusted to change the pressure of the gas (10 to 1000 mbar) and obtain matched major ion current intensities of both reference and sample gases. Each measurement of the sample ion currents is immediately followed by an analysis of the standard's ion currents.

Stainless steel capillaries (1 m length and 0.1 to 0.2 mm i.d.) transport the gas from the variable volumes to the ion source. The *changeover* valve alternately connects the reference and sample bellows to either the ion source or vacuum and the isotope compositions of the two gases are measured in turn. This method ensures a constant flow of gas through the capillaries at all times. To maintain viscous flow conditions, a pressure of ~ 20 mbar in the inlet system is required. This constitutes a lower limit of gas suitable for analysis with the dual inlet system. The smallest practical volume of an inlet system is ~ 250 μ L. This represents 200 nmol of gas at 20 mbar. In some cases, there is not enough sample material available to produce sufficient quantities of gas and alternative analytical methods must be employed, e.g. isotope ratio monitoring.

Delta (δ) Values

In order to realize inter- and intra-laboratory consistency, measured isotope abundance ratios of the sample and reference gases are compared using a δ (delta) scale. In the case of carbon isotope ratio measurements, δ values are calculated as shown in eqn [6]. The δ values for other elements are calculated based on the isotope abundance ratios listed in Table 1.

$$\delta^{13}\text{C} = \left[\frac{(^{13}\text{C}/^{12}\text{C})_{\text{sample}}}{(^{13}\text{C}/^{12}\text{C})_{\text{reference}}} - 1 \right] \times 1000 \quad [6]$$

This quantity is the deviation of the isotope abundance ratio of the sample from that of a standard in parts per thousand or per mill (‰). Positive δ values indicate that the sample is relatively enriched in the heavier isotope of the element with respect to the reference. Negative δ values represent samples that are relatively depleted in the heavier isotope compared to the reference material. The

Table 1 The isotopes that are most commonly compared for the determination of δ values for the elements H, C, N, O and S

Element	Isotope abundance ratio	δ value
Hydrogen	D/H or $^2\text{H}/^1\text{H}$	$\delta\Delta$ or $\delta^2\text{H}$
Carbon	$^{13}\text{C}/^{12}\text{C}$	$\delta^{13}\text{C}$
Nitrogen	$^{15}\text{N}/^{14}\text{N}$	$\delta^{15}\text{N}$
Oxygen	$^{18}\text{O}/^{16}\text{O}$	$\delta^{18}\text{O}$
Sulfur	$^{34}\text{S}/^{32}\text{S}$	$\delta^{34}\text{S}$

National Institute of Standards and Technology (NIST) in Gaithersburg, Maryland, USA and the International Atomic Energy Agency (IAEA) in Vienna, Austria both distribute and continuously calibrate isotope reference materials for a number of elements. The reference materials chosen are representative chemical compounds and reflect nominal terrestrial isotope abundances.

Analysis of H, C, N, O and S Isotope Ratio Variations

Hydrogen and Oxygen

Hydrogen exhibits the largest natural isotope abundance variations due to the relatively large mass difference between its two stable isotopes; ^1H and ^2H (also written commonly as H and D, respectively). H is approximately 99.985% and D 0.015% naturally abundant. The three isotopes of oxygen ^{16}O , ^{17}O and ^{18}O are $\sim 99.763\%$, $\sim 0.0375\%$ and $\sim 0.1995\%$ abundant, respectively. Examples of isotope abundance variations measured for H and O are summarized in Figures 6 and 7.

Hydrogen and oxygen combine to form water and the isotopic species of H_2O vary in mass from 18 to 22 (i.e. H_2^{16}O , to D_2^{18}O). The decreasing vapour pressure with increasing mass of the different isotopomers causes evaporated water vapour in equilibrium with the condensed phase to be relatively enriched in the lighter isotopes of both oxygen and hydrogen. Conversely, the condensation of water from the vapour phase results in a precipitate enriched in the heavier isotopes of O and H (higher $\delta^{18}\text{O}$ and δD values). The condensation of water vapour in equilibrium with its liquid phase – a situation that occurs in clouds – can be described by the Rayleigh fractionation law (eqn [7]).

$$R/R_0 = f^{\alpha-1} \quad [7]$$

Here R_0 is the initial $^{18}\text{O}/^{16}\text{O}$ ratio of the gas phase, R is the actual ratio as a function of the remaining molar fraction in the gas phase (f). The term $\alpha_{\text{liquid-vapour}}$ is the fractionation factor between the liquid and vapour phases at a given temperature. With the increasing amount of ^{18}O -enriched liquid formed and removed from the vapour, the gas phase and liquid phase formed from it

Figure 6 Natural variations in hydrogen isotope abundances. V-SMOW, SLAP, and GISP are international reference water samples available from the International Atomic Energy Agency (IAEA) in Vienna, Austria. V-SMOW = Vienna Standard Mean Ocean Water, SLAP = Standard Light Antarctic Precipitation, GISP = Greenland Ice Standard Precipitation.

Figure 7 Natural variations in oxygen isotope abundances. The $\delta^{18}\text{O}$ values in ancient precipitation (Greenland Ice, Antarctic Ice, etc.) and in foraminiferal carbonate from sediments provide an excellent record of the temperatures of the past.

becomes isotopically lighter. The $\delta^{18}\text{O}$ values for liquid and vapour as a result of this process are plotted in Figure 8. As the precipitation event continues, the immediate removal of the condensed phase from the cloud without any isotope exchange or reevaporation continuously depletes the vapour in D and ^{18}O . As a result, precipitation formed at higher latitudes becomes progressively more depleted in the heavier isotopes of hydrogen and oxygen.

Because the extent of isotope fractionation between the condensed and vapour phases is temperature dependent,

Figure 8 Rayleigh fractionation during water condensation. Condensation starts with the liquid enriched in $\delta^{18}\text{O}$ by 9.2‰ over the gas phase. As the condensation process proceeds, the remaining vapour becomes lighter and, consequently, also the precipitate formed from it.

variations in the δD and $\delta^{18}\text{O}$ values recorded at a particular site reflect seasonal and possibly long-term fluctuations. Ice cores from Greenland, Antarctica, and elsewhere are excellent archives of past climate change, the information recorded mainly in the $^{18}\text{O}/^{16}\text{O}$ ratio of the ice. $\delta^{18}\text{O}$ measurements indicate that very rapid changes from cold to warm and vice versa within a decade have occurred over the past 160 000 years. Such data have challenged our understanding of the underlying processes and caught the attention of the media because of the social and political implications changing climatic events could have today.

Hydrogen and oxygen are also found in many minerals and are fractionated during geochemical processes. The hydrogen and oxygen isotope compositions of the mineral are controlled by the isotope composition of the fluid and the fractionation factor appropriate for the temperature during formation. For example, the $\delta^{18}\text{O}$ value of oxygen in CaCO_3 differs from that of the water as the carbonate precipitates under equilibrium conditions. The extent of fractionation is temperature dependent and at 25°C the mineral is enriched in ^{18}O by about 28‰ compared to the water. The $\delta^{18}\text{O}$ value of carbonates and fluids are used to assess water–rock interactions. Whereas the δD value of hot spring waters may be similar to that of local precipitation, the $\delta^{18}\text{O}$ value may be enriched in ^{18}O indicating oxygen isotope exchange with nearby rocks.

Standards

The standard for both hydrogen and oxygen is V-SMOW (Vienna Standard Mean Ocean Water) distributed by the IAEA in Vienna, Austria. A secondary standard often employed is SLAP (Standard Light Antarctic Precipitation) which has a δD values of -428‰ and $\delta^{18}\text{O}$ values of -55.5‰ with respect to V-SMOW.

Sample preparation

Hydrogen isotopes in water are measured from H_2 gas formed by reducing water with a suitable reducing agent like U, Zn, Cr or C. It is also possible to exchange hydrogen isotopes between H_2 gas and H_2O in the presence of Pt catalysts.

Ratios of HD to H_2 (mass 3 to 2) of the sample hydrogen gas are measured and reported as δD values. Ion–molecule reactions in the mass spectrometer source will result in the production of H_3^+ , which is isobaric with HD^+ at mass 3. The number of H_3^+ ions produced is proportional to the H_2 pressure and to the number of H_2^+ ions in the source, necessitating an empirical correction factor to the measured ratios.

Oxygen isotope compositions of water samples are determined from the measurement of $^{12}\text{C}^{16}\text{O}_2^+$ and $^{12}\text{C}^{16}\text{O}^{18}\text{O}^+$ at masses 44 and 46, respectively. CO_2 gas is equilibrated with 5 mL of water at 25 °C for 8 h and isotope exchange between CO_2 gas and water makes the oxygen isotope composition of the CO_2 gas reflect that of the water.

Carbon

Carbon has two stable isotopes (^{12}C and ^{13}C) of $\sim 98.89\%$ and $\sim 1.11\%$ abundance, respectively. Carbon compounds are exchanged between the oceans, atmosphere, biosphere and lithosphere. Significant isotope ratio variations exist within these groups due to both kinetic and equilibrium isotope effects. Representative carbon isotope abundance variations are shown in **Figure 9**.

During photosynthesis, the metabolized products become depleted in ^{13}C compared to the CO_2 . The initial assimilation and intracellular diffusion of CO_2 in the plant produces a 4 ‰ depletion in its $\delta^{13}\text{C}$ value. Isotope fractionation during the decarboxylation of the absorbed CO_2 is dependent on the plant species and causes a much larger shift in the $\delta^{13}\text{C}$ value. Plants that form a 3-carbon phosphoglyceric acid as the first product of carbon fixation according to the Calvin cycle (commonly referred to as C_3 plants) have $\delta^{13}\text{C}$ values averaging -28‰ V-PDB. Examples of C_3 plants include cereal grains, peanuts, rice, tobacco, beans, sugar beets and all evergreen and deciduous trees. Plants that photosynthesize dicarboxylic acid by the Hatch–Slack mechanism (referred to as C_4 plants) are more enriched in ^{13}C and have $\delta^{13}\text{C}$ values closer to -13‰ V-PDB. C_4 plants include corn,

Figure 9 Natural variations in carbon isotope abundances. North American diet to a large extent is derived from maize, a C_4 plant. In countries like Japan, where fish is a major part of the average diet, $\delta^{13}\text{C}$ values are in between the European and North American values.

millet, sorghum, sugar cane and many grasses such as crab grass and bermuda grass. Crassulacean acid metabolism (CAM) plants have intermediate $\delta^{13}\text{C}$ values. This arises because they metabolize CO_2 via C_3 pathways in light and C_4 in darkness. The large isotope fractionations that arise in plants are generally retained as the organic material is incorporated into sediments and eventually as hydrocarbon deposits.

The carbon isotope composition of food ingested by animals is generally reflected in the metabolized products. For example, it is possible to differentiate between animals that have primarily C_3 versus C_4 diets based on the measurement of the $\delta^{13}\text{C}$ value of hair, finger nails, bone collagen, etc. This information is useful in food web studies to determine primary nutrient sources and to discover who is the prey and who the hunter. Nitrogen isotopes are often combined with $\delta^{13}\text{C}$ data for a comprehensive trophic level analysis.

Oceans play a significant role in the exchange of CO_2 between the atmosphere and biosphere. Carbon isotope exchange between CO_2 in the air and HCO_3^- in the oceans results in ^{13}C enrichment of the latter. CO_2 in air is well mixed globally and currently has a $\delta^{13}\text{C}$ value of -8‰ V-PDB compared to marine limestones at $\sim 0\text{‰}$ V-PDB. Freshwater carbonates have much more variable and lower $\delta^{13}\text{C}$ values due to the oxidation of ^{13}C depleted organic matter and subsequent formation of HCO_3^- .

The CO_2 content of the atmosphere has increased dramatically due to the combustion of fossil fuels and oxidation of soil and organic matter. Fossil fuels are generally depleted in ^{13}C because they were derived from organic material. Consequently, the global $\delta^{13}\text{C}$ value of atmospheric CO_2 has seen a change from 6.5‰ in preindustrial times to about 8.0‰ today.

Standards

The standard for carbon isotope abundance measurements is based on a Cretaceous belemnite sample from the Peedee formation in South Carolina, USA. The original material is no longer available. It has been replaced by the convention that NBS 19, a carbonate material, has a value of $+1.95\text{‰}$ versus PDB. This new scale is termed V-PDB (Vienna-PDB). The IAEA distributes a number of secondary standards including graphite (USGS24) with a $\delta^{13}\text{C}$ value of -15.99‰ V-PDB, oil (NBS-22) at -29.74‰ V-PDB, and calcium carbonate (NBS-18) with a value of -5.01‰ V-PDB.

The oxygen isotope composition of carbonates is also commonly referenced to the $^{18}\text{O}/^{16}\text{O}$ -isotope ratio of V-PDB. It is not used as a reference for $\delta^{18}\text{O}$ analyses of igneous or metamorphic rocks. The difference between V-SMOW and V-PDB $\delta^{18}\text{O}$ values is approximately 30‰ ($\delta^{18}\text{O}_{\text{V-SMOW}} = 1.03091 \times \delta^{18}\text{O}_{\text{V-PDB}} + 30.91$).

Sample preparation

CO_2 gas is produced from carbonate minerals by reaction with $100\% \text{H}_3\text{PO}_4$ or by thermal decomposition. The carbon and oxygen isotope compositions of the carbonate can be determined simultaneously from the CO_2 produced. $\delta^{13}\text{C}$ values from organic samples are analysed by combusting the material at high temperature with an oxygen source (commonly CuO) in sealed quartz tubes. Ion currents at mass 44, 45 and 46 produced from CO_2 gas are measured in order to determine a $\delta^{13}\text{C}$ value. The isobaric interference at mass 45 from ^{17}O (i.e. both $^{13}\text{C}^{16}\text{O}^{16}\text{O}^+$ and $^{12}\text{C}^{17}\text{O}^{16}\text{O}^+$ will be collected by the same Faraday detector) requires an empirical correction to enable the calculation of the $^{13}\text{C}/^{12}\text{C}$ ratio from the measured mass 45 (^{17}O correction).

Nitrogen

Nitrogen is present primarily as N_2 gas in the atmosphere and dissolved N_2 in oceans. In terrestrial systems, nitrogen is found in minor amounts bound to H, C and O in both reduced and oxidized states. Nitrogen has two stable isotopes ^{14}N and ^{15}N of $\sim 99.64\%$ and $\sim 0.36\%$ abundance, respectively. Isotope abundance variations measured for nitrogen are summarized in **Figure 10**.

Biochemical reactions mediated by bacteria are responsible for many nitrogen isotope fractionations. The fixation of N_2 gas to compounds such as NH_3 at the nodules of plant roots requires substantial energy to break the N_2 bonds and results in negligible isotope fractionation. However, the conversion of ammonia to nitrates (nitrification) initially to NO_2^- by *Nitrosomonas* ssp. and then to NO_3^- by *Nitrobacter* yields nitrates that can have $\delta^{15}\text{N}$ values 20‰ more negative than the ammonia. The bacterial conversion of nitrates to N_2 under anaerobic conditions (denitrification) by *Pseudomonas*

Figure 10 Natural variations in nitrogen isotope abundances. $\delta^{15}\text{N}$ values are often used to establish the position of a particular species within the food chain of an ecosystem (trophic level).

denitrificans or *Thiobacillus denitrificans* enriches the ^{15}N content of the residual nitrate increasing the $\delta^{15}\text{N}$ value by as much as 30‰ as the reaction progresses. Generally, the organic matter of the biosphere is enriched in ^{15}N compared to the atmosphere and $\delta^{15}\text{N}$ values for marine environments are greater than those measured in continental regions.

Increasing populations and agricultural activities have a significant influence on the amount of nitrate in groundwater. Within a given region, nitrate concentrations and $\delta^{15}\text{N}$ values can be used to trace the source of anthropogenic nitrogen compounds into a system and monitor its occurrence over time.

The relationship between the nitrogen isotope composition of an animal and its position in the food chain is such that one observes an increase in the $\delta^{15}\text{N}$ value of approximately 3‰ per trophic level. Compared to the food source, excreted nitrogen is relatively depleted in ^{15}N due to fractionation during urea formation. The analysis of contemporary and archaeological specimens of feathers, bone, hair or skin can provide information about the diets of people and animals and changes that may have occurred in response to past climatic or historical events.

Standards

Nitrogen in the atmosphere is well mixed and $\delta^{15}\text{N}$ values are reported relative to the isotope composition of N_2 in air.

Sample preparation

Nitrogen isotope abundances are determined by measuring ions at masses 28 ($^{14}\text{N}^{14}\text{N}^+$) and 29 ($^{14}\text{N}^{15}\text{N}^+$). Nitrogen compounds are converted to N_2 gas by high temperature combustion in an elemental analyser. N_2 gas introduced into the ion source must be free from CO or CO_2 that produce an isobaric interference at masses 28 and 29.

Figure 11 Natural variations in sulfur isotope abundances. Large sulfur isotope fractionations are possible during the reduction of sulfates to sulfides by anaerobic bacteria that produce ^{32}S enriched H_2S relative to the original sulfate.

Sulfur

Sulfur has four stable isotopes: ^{32}S , ^{33}S , ^{34}S and ^{36}S which are ~95.02%, ~0.75%, ~4.21% and 0.02% abundant, respectively. Sulfur is ubiquitous in the global environment and major sulfur reservoirs include sulfate in the oceans, evaporites, sulfide ore deposits, and organic sulfur compounds. Sulfur isotope abundance variations are shown in Figure 11.

Large kinetic isotope effects occur during the reduction of sulfate by anaerobic bacteria such as *Desulfovibrio* ssp. resulting in the product sulfide having $\delta^{34}\text{S}$ values ranging from +3 to -46‰ with respect to the remaining sulfate. Another potential mechanism for sulfur isotope fractionation includes exchange reactions among sulfur compounds with S in different valence states. For example, sulfur isotope exchange between sulfate and sulfide (and resulting change in oxidation state from +6 to -2) is predicted to yield fractionations as large as 75‰ between the H_2S and SO_4^{2-} at 25°C. However, sulfur isotope exchange between sulfates and sulfides proceeds very slowly and probably occurs at high temperature where the equilibrium constant is close to unity. Sulfur oxidation, mineral precipitation, and high temperature processes result in less extensive isotope fractionations.

Sulfur isotope compositions are employed to assess the effect of industrial activities in pristine environments, particularly in regions where the pollutant sulfur has a distinct $\delta^{34}\text{S}$ value compared to that of the environmental receptors. For example, in the province of Alberta, Canada, emissions from sour gas processing plants have $\delta^{34}\text{S}$ values 20‰ higher compared to sulfur isotope compositions of unaffected soils. The distinct isotope composition of the anthropogenic sulfur allows it to be followed as it enters the environment via biogeochemical reactions.

Standards

The international sulfur isotope scale is based on a troilite sample from the Canyon Diablo meteorite, termed CDT. The International Atomic Energy Agency (IAEA) in Vienna has promoted the use of a more accurate sulfur isotope scale, V-CDT, to replace CDT because of isotopic inhomogeneities of $\pm 0.4\text{‰}$ in the original sample. A new Ag_2S standard, IAEA S-1, has a defined $\delta^{34}\text{S}$ value of -0.30‰ V-CDT.

Sample preparation

Sulfur isotope abundances are measured commonly from isotopic ion currents of SO_2^+ at masses 64, 65 and 66. SO_2 gas is generated by reacting sulfur or sulfide minerals with V_2O_5 and SiO_2 in a ratio of 1:10:10 in sealed quartz tubes heated to 900°C . Isobaric interference from oxygen isotopes necessitates the preparation of SO_2 from standards and samples with identical oxygen sources. SO_2 is easily adsorbed onto glass and metal surfaces and care is required in its handling to avoid fractionation and memory effects among different samples. An alternative (and lesser used) approach is to form the more stable SF_6 gas and measure SF_5^+ ions.

Isotope Ratio Monitoring

An analytical technique for high precision, high sensitivity isotope ratio measurements is isotope ratio monitoring (*irm*). The *irm* instrument is a further development of the classical isotope ratio mass spectrometer including improvements in source design, vacuum pump technology, high speed detection electronics and powerful personal computers for data processing. This method for isotope analysis does not employ a dual inlet (**Figure 1**) and hence there is no requirement to generate large amounts of sample gas to maintain viscous flow conditions in the capillaries. Instead, isotope abundance data are extracted from time-varying ('transient') signals as opposed to measurements of prepared gases stored in reservoirs that produce near constant signal intensities. The entire sample entrained in a helium carrier gas enters the ion source as a transient and is ionized for isotope abundance measurements. A typical *irm* chromatogram for D/H analysis from GC eluates is shown in **Figure 12**. All ion currents of interest are integrated as the He carrier sweeps the sample through the source. A pulse of reference gas is admitted to the source and its isotope ratio determined in a similar manner. From the two measurements the δ value of the respective sample peak is calculated. Advantages of the *irm* technique include the smaller amount of sample that must be prepared for analysis (1 nmol compared to 200 nmol). In addition, reduced sample handling and preparation is possible because raw materials are converted to simple

gases for analysis by automated sample preparation devices (such as elemental analysers). It should be noted that there are a number of terms in current use in the literature to describe this method, including continuous flow isotope ratio mass spectrometry or CF-IRMS.

Configuration of *irm* Inlet Systems

The *irm* system consists of three components: the sample preparation device, isotope ratio mass spectrometer and the gas and electronic interface between the two. Depending on the nature of the sample and type of analysis required, there are two approaches to assembling an *irm* inlet system (**Figure 13**). For isotope abundance ratio determinations from bulk samples, the entire sample is either oxidized or pyrolysed, producing a mixture of reaction products (CO_2 , N_2 , SO_2 and H_2O for the oxidation, CO and H_2 for the pyrolysis) that must be separated prior to introduction into the mass spectrometer. In contrast, compound specific analysis is the separation of a particular component from some complex mixture followed by conversion to a gas suitable for isotope analysis (by oxidation or pyrolysis) and subsequent introduction into the mass spectrometer ion source. Here, reaction products are isolated by chemical means on-line when possible.

The amount of sample and carrier gas that enters the ion source is limited to a maximum of about 0.5 mL min^{-1} . Therefore, only a portion of the gas from the sample preparation device is admitted, requiring an open split. A high gas flow from the preparation system will require a higher split ratio and reduce the relative amount of sample available for ionization. To maximize sensitivity the split ratio should be as low as practically possible thereby maximizing the amount of sample ionized.

Bulk composition isotope ratio monitoring

The determination of isotope compositions from bulk samples is one of the most widespread applications of *irm* techniques primarily because of its ease of use, possibility for automated analysis, and the variety of sample types that can be analysed. Raw samples are most often converted to simple gases by an elemental analyser (EA) where submilligram quantities of sample are packed into Sn or Ag capsules ($2 \times 5 \text{ mm}$) and loaded into the auto-sampler of the EA. Carrier gas flow rates are typically 80 to 120 mL min^{-1} , necessitating a high split ratio at the mass spectrometer. Individual samples are dropped into an oxygen-enriched He stream sweeping a reactor at 1050°C where they are combusted instantaneously. A second copper-filled furnace at 600°C in-line reduces nitrogen oxides produced in the combustion process to N_2 gas. It also scavenges excess oxygen not used in the combustion. Water is removed from the combustion products and the CO_2 , N_2 and SO_2 (if any) are separated by a packed column (**Figure 14**).

Figure 12 *irm*-GCMS chromatogram from a crude oil extract. The isotope ratio of deuterium versus hydrogen from a post column high temperature (1400 °C) pyrolysis reaction is studied. The lower trace shows the mass 2 intensity whereas the upper trace exhibits the instantaneous intensity ratio of 3/2 as a function of time. The deuterated compounds elute earlier than the nondeuterated ones with a time shift between 1 and 5 s. This gives rise to the marked isotope swing in the upper 'ratio' trace. The first 3 peaks are reference gas pulses injected behind the GC, thus they do not exhibit this behaviour. Here, differences in the amplifier time constants give rise to the sharp edges displayed on the ratio trace.

Compound specific isotope ratio monitoring

The isotope composition of individual components constituting a complex mixture can be determined by separating out the individual fractions followed by conversion into simple gases suitable for analysis. The basic arrangement is a gas (or liquid) chromatograph followed by an oxidation (or pyrolysis) furnace and open split to the mass spectrometer (**Figure 15**). A capillary chromatographic column first separates the mixtures.

For oxidation and carbon or nitrogen isotopic analysis the components are then swept sequentially through a furnace converting them to N_2 , CO_2 and H_2O . Water is removed and CO_2 is removed cryogenically if $\delta^{15}N$ measurements are to be made. For $\delta^{13}C$ analysis alone, nitrogen, if present, also enters the ion source. It does not interfere with the measurement.

For pyrolysis at high temperatures (δD or $\delta^{18}O$ analysis) the gaseous reaction products H_2 and CO are allowed to enter the mass spectrometer simultaneously. For D/H it is possible to remove CO cryogenically using,

for instance, a piece of capillary molecular sieve column immersed in liquid nitrogen.

The low carrier gas flow ($< 3 \text{ mL min}^{-1}$) allows for a low split ratio or high sensitivity. This technique termed *irm*-GCMS is sometimes referred to as gas chromatography–combustion mass spectrometry (GCCMS).

Characteristics of the *irm* Mass Spectrometer

The *irm* mass spectrometer must be able to handle the resulting high pressures in the ion source region (10^{-5} mbar) while processing data from transient signals with precisions comparable to, or better than, dual-inlet performance. Differential pumping of the source and analyser regions enables the ion source of the *irm* instrument to operate under a high continuous He load.

To measure nanomoles of gas, the mass spectrometer ion source must maximize the number of ions detected per number of gas molecules introduced. Typical *irm* instruments are capable of producing 1 ion for every 1500

Figure 13 Comparison of isotope ratio monitoring (*irm*) sample preparation and introduction for bulk versus compound specific sample analysis. In bulk sample analysis, the GC follows the combustion step whereas in the compound specific *irm* system CO_2 and N_2 from a single peak both enter the mass spectrometer at the same time. In both cases the amount of gas flowing to the ion source is comparable. The difference in sensitivity comes from the difference in carrier gas flow rate (about 100 mL min^{-1} versus $\sim 1.5 \text{ mL min}^{-1}$).

molecules admitted to the source. In practice, this is achieved by using a 'closed' source design and allowing a large angle of the ion beam to enter the analyser region of the mass spectrometer. The ion optical design of the instrument ensures that the vertical height of the ion beam is identical at the entrance and exit slits so that loss of ions due to collisions with the walls of the flight tube is minimized.

The transient signals encountered in *irm* mass spectrometry vary over several orders of magnitude during an analysis. In order to measure accurate isotope abundance ratios, the measured ion current ratios must not depend on the ion current intensities. This characteristic is defined as source linearity. Note that with dual-inlet systems, major ion current intensities of the sample and reference gases were matched by varying the pressure of the gas in the ion source to counter errors introduced by nonlinear source behaviour. Two major causes of

Figure 14 Bulk sample isotope ratio monitoring interface. The means for reference gas injection and for effluent dilution are not shown.

Figure 15 Compound specific isotope ratio monitoring interface. For clarity, the devices for backflushing the solvent, for effluent diversion from the ion source, and for reference gas injection are not shown.

nonlinear source behaviour are the buildup of space charge due to the large numbers of He atoms in the source and the reaction of neutrals with protonating agents leading to isobaric interference.

The Faraday cups receive a constant stream of time-varying ion currents that must be processed without loss of data. This capability was only possible with the development of high speed, low cost personal computers. Ion currents are converted to voltages by high gain, low noise operational amplifiers. The voltages are then digitized into signals that can be processed by a computer. Typically, the voltage is integrated over 0.25 s time slices and converted to a frequency pulse such that the

number of pulses within the interval is directly proportional to the measured ion current. The time constants of the ion current amplifiers (i.e. how quickly the device responds to a changing signal) are optimized and matched for all detectors.

Examples of *irm* Applications

Doping in athletics

Testosterone is a potent performance-enhancing drug that is used in both human and equestrian sports. The current method to detect testosterone abuse is based on measurement of the testosterone to epi-testosterone ratio using GC or LC/MS techniques. However, this method is not reliable because some 'clean' individuals may naturally register a 'positive' result and the measurement must be made no more than 5 h after ingestion of the drug. Successful detection of drug abuse by *irm* is possible because commercially available testosterone has a lower $\delta^{13}\text{C}$ value than that metabolized by the body (approximately 5‰ lower). The isotope ratio determination of a subject's testosterone and metabolites by *irm*-GCMS can detect this shift in $\delta^{13}\text{C}$ values and detect testosterone abuse 24 h after the initial dose.

Food adulteration

Quality assurance of food products is an important activity in the food industry where the substitution of lower cost alternatives constitutes fraud as well as a public health risk. Stable isotope measurements have been successfully applied to many instances where 'all-natural' fruit juices, honey and maple syrup have been artificially sweetened. This is possible when the added sugar is from a plant species which follows a different photosynthetic pathway from that of the bulk material (C_3 versus C_4 plants), leading to a $\delta^{13}\text{C}$ composition of the food product intermediate to the 12‰ difference between the two plant types.

The determination of the $\delta^{13}\text{C}$ value of individual fatty acids of adulterated and unadulterated maize oils by *irm*-GCMS allows as little as 5% of an adulterant C_3 oil to be detected. More recently, the measurement of $\delta^{18}\text{O}$ value of olive oils that were pyrolysed over nickelized carbon demonstrated a geographical dependence between ^{18}O and latitude. Lower $\delta^{18}\text{O}$ values were measured for olive oils coming from Italy as compared to Greece, allowing the origin of the product to be verified.

Detection of *Helicobacter pylori*

The *Helicobacter pylori* bacterium is found in the mucous membrane of the stomach and is the major cause of gastritis, gastric ulcers and cancer of the stomach and duodenum. It produces urease that cleaves urea to form ammonia and CO_2 . The detection of this dangerous bacterium is possible by administering a small amount (100 mg) of ^{13}C -labelled urea to the patient and measuring the $\delta^{13}\text{C}$ value of breath CO_2 . If after 30 min an

increase in the $\delta^{13}\text{C}$ of the breath- CO_2 is detected, the bacterium is present and actively forming ^{13}C -enriched CO_2 from the labelled urea. This noninvasive procedure is simple to administer and is widely applied as a ^{13}C urea breath test by a number of medical laboratories.

Trace gas analysis in air

Greenhouse gases such as methane, CO_2 and N_2O are causing the temperature of the planet to increase, or they are interfering with ozone chemistry in the stratosphere. Isotope analysis of these gases may help to understand their cycling in the atmosphere or between global pools. For CH_4 and N_2O , dual inlet techniques require in excess of 70 L of air to achieve the precision ($\pm 0.2\%$ for $\delta^{13}\text{C}$, $\delta^{18}\text{O}$ and $\delta^{15}\text{N}$) required to discriminate among different sources. Such large samples are difficult to process and are of low spatial and temporal resolution. To obtain meaningful, high resolution data from modern and archived air samples, *irm* techniques have been developed which are capable of analysing the isotope composition of CH_4 (1.7 ppm) and N_2O (0.3 ppm) in 25 mL and 100 mL air samples, respectively.

As is well known, an atomic nucleus is characterized by its positive charge Z (an integer that designates the number of fundamental electric charges) and its mass. Nuclear masses are so close to being multiples of the proton rest mass that they are also characterized by integers, A . The integers A and Z characterize a nuclide. Most elements as found in nature contain mixtures of nuclides with different values of A , known as isotopes.

Pure isotopes have masses that differ measurably from the integers A (based on a scale on which ^{12}C has a mass defined as 12.000 00 atomic mass units or amu). None of the stable nuclides (i.e. those with nuclear half-lives $>10^9$ years) deviates from integer mass by more than 0.1 amu. The nominal mass of a molecule is the sum of the A values of its constituent atoms.

Labelling Nuclides

In 1914 F.W. Aston demonstrated mass spectrometric separation of the two most abundant isotopes of neon. Since that time, careful measurement has established that 20 chemical elements are monoisotopic (i.e. exhibit only one naturally occurring stable nuclide to any significant extent). From the remaining members of the periodic table, the relative abundances for hundreds of isotopic pairs (same Z , different A) have been determined by mass spectrometry. The 163 stable nuclides for elements lighter than xenon give rise to slightly more than 300 isotopic pairs.

Labelling embraces those experimental designs in which two nuclides have been mixed under conditions in which they might be expected to behave identically (or nearly so), followed by an analysis that distinguishes them. Usually the mass spectrometer acts as the analyser,

but it can play the role of the mixer instead. A measurement of the ^{44}Ti half-life (a piece of data pivotal for investigating astronomical cataclysms) illustrates one such application in nuclear physics. Bare nuclei with the same A/Z ratio will coincide in a mass separator. At gigavolt kinetic energies, where ions undergo nuclear reactions with target atoms and emerge without any bound electrons, ions from different elements having $A=2Z$ will not be separated but can be isolated from those for which $A\neq 2Z$. This technique has been used to implant mixtures of ^{22}Na and ^{44}Ti simultaneously into solid matrices, where the radioactive sodium provides a standard for measuring the decay rate of the radioactive titanium. In this example, one nuclide has been used to label another that has very different chemistry, so as to provide a well-calibrated mixture of the two.

More conventionally, mass spectrometry is used to separate isotopes of a given element or isotopically tagged compounds. Four stable isotopic pairs have found application in the vast majority of molecular labelling experiments examined by mass spectrometry – $^1\text{H}/^2\text{H}$, $^{12}\text{C}/^{13}\text{C}$, $^{14}\text{N}/^{15}\text{N}$, and $^{16}\text{O}/^{18}\text{O}$. In each of these cases, the heavier isotope is the rarer, with natural abundances of 0.15% (^2H), 1.1% (^{13}C), 0.37% (^{15}N), and 0.20% (^{18}O). The survey below will confine itself to molecular labelling experiments that utilize hydrogen, carbon, nitrogen and oxygen isotopes.

Isomers, Isotopomers and Isobars

The term isomer has two different meanings, only one of which will pertain here. The meaning that is not relevant is employed by physicists, to whom *nuclear* isomers designate states of atomic nuclei with the same A and Z (generally having different net spins), which have different masses. For example, two nuclear isomers of cadmium, ^{113}Cd and $^{113\text{m}}\text{Cd}$, differ in mass by 0.0003 amu. Nuclear isomers will be omitted from further mention. Isomerism will refer below only to molecules that possess the same atomic composition but different atomic connectivities.

The term isotopomer designates a variant of a molecule with a different net isotopic content. Except for the isotopic difference, the two molecules must otherwise have identical structures. Three isotopomers of phenol provide an example. The (^{13}C)phenol drawn as structure

[1] represents an isotopomer of phenol containing only ^{12}C . But [1] is not an isotopomer of structure [2], which also contains one ^{13}C . Instead [1] and [2], properly speaking, are *isotopic isomers*, differing only by the placement of the labelled atom.

Ions with different elemental compositions may display the same nominal mass-to-charge ratio (m/z), such as the m/z 28 positive ions $\text{N}_2^{+\bullet}$, $\text{CO}^{+\bullet}$, $\text{C}_2\text{H}_4^{+\bullet}$, HCNH^+ , Fe^{2+} , and Ce^{5+} . These are sometimes called isobars. Among physicists, *isobars* denote two nuclides with the same value of A but different values of Z . Chemists use the term less restrictively. The monodeuterated phenol [3] is an isotopomer of [1] and [2]. If all of its carbons are ^{12}C , then the mass of [3] will have the same integer value as the masses of [1] and [2], and all three molecular ions will have m/z 95. [3] is an *isobaric isotopomer* of [1] and [2]. The deuterated ion does not have the same mass as the ^{13}C -containing ions, and they can be distinguished by high-resolution mass spectrometry (HRMS).

Mass spectrometry cannot separate the molecular ions of isomers, although two isotopic isomers might well give rise to different fragmentation patterns (see below). Mass spectrometry can separate isotopomers, even if they happen to have the same nominal mass. **Figure 1** illustrates a published example, an experimental measurement of the abundances of m/z 95 fragment ions from a larger molecule. Phenol ($\text{C}_6\text{H}_5\text{OH}$) tagged with a single ^{13}C atom corresponds to any one of four isomers (including [1] and [2]) with identical masses, or a mixture thereof. Monodeuterated phenol has the same nominal mass as (^{13}C)phenol. The positive-ion mass spectrum reproduced in **Figure 1** displays the resolution of the two isotopomers (which differ by 0.003 amu) as well as protonated phenol ($\text{C}_6\text{H}_7\text{O}^+$), which has a different elemental composition.

The techniques that give the highest resolution (such as Ion Cyclotron Resonance (ICR) MS) do not enjoy a reputation for accurate quantitation of isobars. Double focusing sector mass spectrometers (such as was used for the mass spectrum in **Figure 1**) appear to be the current method of choice for experiments that require high-resolution measurements of relative ion abundances, even though they have lower resolving power. It is important to bear in mind the distinction between high-resolution mass spectrometry (as exemplified by **Figure 1**) and

Figure 1 HRMS of m/z 95 ions from 70 eV electron ionization of $\text{C}_6\text{H}_5\text{OCH}_2\text{CD}_2\text{OH}$, illustrating the resolution of isobaric ions on a double focusing reverse Nier–Johnson (B–E) instrument with resolving power of 70 000. Each of the peaks that contains a rare isotope is a radical ion (odd number of electrons), which is a mixture of isomeric structures, all the possibilities for which are drawn. Asterisks designate ^{13}C -containing positions of the ring. The unlabelled ion is an even-electron species. Reproduced from Nguyen V, Bennett JS, and Morton TH (1997) *Journal of the American Chemical Society* 119: 8342 with permission of the American Chemical Society with modifications.

exact mass determination (for which ICR gives excellent results based on accurate frequency measurements).

Variations of Natural Abundances

Precise measurement of relative natural abundances finds application in chemistry. The food industry routinely assays $^{12}\text{C}/^{13}\text{C}$ ratios of flavourings in order to ascertain their origin. For instance, that isotopic ratio is slightly greater for synthetic vanillin than for the identical molecule from the vanilla bean. As the commercial value of natural vanillin is approximately one million times greater than that of the synthetic, isotope ratio mass spectrometry (IRMS) plays a major role in quality control.

Isotopes do not fractionate identically among the products of most chemical reactions. If a reaction proceeds in 100% yield, the net balance of isotopes in the products ought to be identical to that of the reactants, though the distribution may differ between two products. When a reaction does not run to completion, the natural abundance in the products may vary appreciably from that of the reactants. Measurement of the distribution of natural-abundance isotopes represents an important tool in studying reaction pathways, but the partitioning does not always depend solely upon isotopic mass. In 1978 B. Kraeutler and N.J. Turro used mass spectrometry to

determine the fractionation of ^{13}C in carbon monoxide from decomposition of the radical pair produced by photolysis of dibenzyl ketone (eqn [1]).

The nuclear magnetism of the heavier carbon isotope perturbed the branching ratio under the reaction conditions, favouring return of the intermediate caged radical pair to the starting material. Hence, recovered CO was measurably depleted in ^{13}C . In part, the elegance of this experiment derives from the fact that it required no synthesis or separation of isotopically enriched starting material. In 1980 R.G. Lawler pointed out that conclusive demonstration of nuclear spin isotope effects demands bracketing of the magnetic isotope between two non-magnetic ones (e.g. depletion of ^{13}C relative to ^{14}C as well as depletion relative to ^{12}C); however, few experiments have been reported that fulfil this rigorous requirement.

Isotopic Dilution and Tracer Techniques

Isotopic dilution and tracer techniques represent different methodologies, but they overlap to a degree that obviates any clear-cut categorization. Both are techniques for quantitative analysis. In an isotopic dilution experiment one adds a known amount of an isotopomer (sometimes called the 'spike') of a known compound (usually containing a rare isotope) and measures the abundance of ions derived from it relative to those from the analyte (which is usually the more common isotopomer). If, for example, one wished to quantitate phenol ($\text{C}_6\text{H}_5\text{OH}$) in a mixture, one might add a known quantity of pentadeuterated phenol ($\text{C}_6\text{D}_5\text{OH}$) as a spike and measure the m/z 94: m/z 99 intensity ratio by mass spectrometry.

This conceptually simple approach, called a mass isotopomer abundance ratio (MIAR) measurement, requires a number of refinements. First of all, other components of the mixture might give rise to ions of the same mass – for instance, all alkyl phenyl ethers larger than anisole give very prominent m/z 94 ions. Therefore, MIAR experiments ordinarily require chromatographic separation prior to mass spectrometry (such as GC-MS), an approach sometimes referred to as isotope ratio monitoring (IRM) chromatography MS. Since different isotopic variants may have slightly different retention times, one must monitor intensity ratios over the entire elution profile of the component under analysis. Second, isotope effects may alter the relative abundances of fragment ions; hence, calibration with authentic samples is necessary. Finally, MIAR measurements give best results when the peaks to

be compared have comparable intensities. When one ion has abundance more than an order of magnitude greater than the other, interferences and nonlinearities begin to introduce uncertainty and the measured MIAR may depend upon the amount of sample introduced into the mass spectrometer. C.K. Fagerquist and J.-M. Schwarz have surveyed the origins of systematic deviations and list ion-molecule reactions within the mass spectrometer and detector nonlinearities as possible sources of error.

The most reliable abundance measurements involving stable isotopes make use of carbon, nitrogen or oxygen labelling, with chromatographic separation followed by quantitative conversion to light gases prior to mass spectrometric measurement. GC-combustion-isotopic dilution MS (GC-C-IDMS) depends upon the high precision with which isotopic abundances for CO_2 and N_2 can be measured by means of isotope ratio mass spectrometry. Oxygen has three stable isotopes, and ^{13}C natural abundance interferes if one wishes to analyse ^{17}O content in CO_2 . For such purposes, CO_2 can be converted to molecular oxygen with 5% molecular fluorine in helium. The basic equation for IDMS (regardless of whether the mass analysis is performed on the intact molecule or on its degradation products) is

$$N^{\text{sample}} = N^{\text{spike}} \frac{(R^{\text{spike}} - R^{\text{blend}}) \sum R_i^{\text{sample}}}{(R^{\text{blend}} - R^{\text{sample}}) \sum R_i^{\text{spike}}} \quad [2]$$

where N^{spike} stands for the (known) number of moles of spike; N^{sample} stands for the number of moles of analyte (to be quantitated); R^{spike} stands for the observed peak intensity ratio for the pure spike substance; R^{sample} stands for the observed peak intensity ratio for the pure analyte; R^{blend} stands for the observed peak intensity ratio for the mixture of spike and sample; and R_i stands for the observed ratios for all isotopomers.

The following worked example illustrates how to apply eqn [2]. Consider an unknown number of moles of analyte (N^{sample}) for which the observed ^{13}C : ^{12}C peak intensity ratio is $R^{\text{sample}} = 1/9$, to which one adds a known number of moles of spike (N^{spike}), for which the observed ^{13}C : ^{12}C peak intensity ratio is $R^{\text{spike}} = 2/1$. Suppose the observed ^{13}C : ^{12}C peak intensity ratio for the mixture is $R^{\text{blend}} = 23/37$. The values to be summed in the numerator are $\sum R_i^{\text{sample}} = 1/9 + 1$, the sum of the ^{13}C : ^{12}C peak intensity ratio and the ^{13}C : ^{13}C peak intensity ratio for the pure analyte. The values to be summed in the denominator are $\sum R_i^{\text{spike}} = 2/1 + 1$, the sum of the ^{13}C : ^{12}C peak intensity ratio and the ^{13}C : ^{13}C peak intensity ratio of the pure spike. Inserting these values into eqn [2] gives

$$N^{\text{sample}} = N^{\text{spike}} \left[\frac{(2/1 - 23/37)(10/9)}{(23/37 - 1/9)(3)} \right] \\ = N^{\text{spike}}[1] = N^{\text{spike}} \quad [3]$$

Scheme 1

In other words, the example corresponds to the outcome for equal amounts of sample and spike.

The above instance might obtain when the sample has nine carbon atoms (containing natural-abundance ^{13}C) and the spike has one partially labelled atom (though the spike might contain a mixture of isotopic isomers). Quantitation becomes more reliable if naturally occurring isotopomers do not overlap the peaks from the spike, so that $R^{\text{sample}} \rightarrow 0$. Multiple labelling can adequately address that issue. Also, precision increases as the isotopic purity of the spike is increased, so that $R^{\text{spike}} \rightarrow \infty$. Strictly speaking, it is not the values of R^{sample} and R^{spike} that introduce error, but rather the uncertainty in measuring those ratios when they do not have their limiting values of zero and infinity.

In tracer studies, the analyte is not present at the time the spike is added. Diagnosis of human infection by *Helicobacter pylori* (the bacteria implicated in digestive tract ulcers) exemplifies such a technique. This micro-organism survives at low pH in the stomach by generating locally high concentrations of ammonia to buffer its immediate environment. When a patient swallows a sample of ^{13}C -labelled urea, a colony of these bacteria (if present) will hydrolyse the urea to NH_3 and CO_2 , giving a characteristic rate of production of ^{13}C -carbon dioxide in the patient's breath.

The distinction between tracer and isotope dilution methodologies is often blurred. For instance, IDMS sometimes requires a series of chemical transformations. A recently published protocol for quantitating nitrate in environmental samples dilutes the sample with $^{15}\text{NO}_3^-$ followed by a series of steps that reduce it to nitrite and then convert it to an azo dye, Sudan I, as Scheme 1 summarizes. Derivatization of label-containing Sudan I to its *t*-butyldimethylsilyl (TBDMS) ether then renders the labelled molecule sufficiently volatile to be introduced into a mass spectrometer. The ratio of $M-57$ fragment ion intensities quantitates the $^{15}\text{N}/^{14}\text{N}$ ratio, once

correction has been made for ^{29}Si (natural abundance 5% that of ^{28}Si) and ^{13}C natural abundance of the 18 carbons in the ion.

A physiological labelling technique that applies tracer and isotopic dilution methodologies concurrently involves the use of doubly labelled water (containing ^{18}O in addition to a heavy isotope of hydrogen) for metabolic studies. After an animal is dosed with doubly labelled water, part of the labelled oxygen turns up in exhaled CO_2 . From the amount of ^{18}O tracer in the CO_2 and the proportions of ^{18}O and isotopic hydrogen in excreted water (the isotopic dilution), one can infer the rate of energy expenditure of a living organism.

Quantitative analysis of tracer experiments can be more complicated than for isotopic dilution. Consider a hypothetical outcome for pure H_2^{18}O mixed thoroughly with a 10-fold excess of pure H_2^{16}O , where all of the oxygen atoms (and only those oxygen atoms) turn up in recovered CO_2 . Statistically, the carbon dioxide should exhibit a distribution of zero, 1, or 2 labelled oxygens in the proportions $m/z \text{ 44}: m/z \text{ 46}: m/z \text{ 48} = 100:20:1$. It is clear that eqn [2] is not the right expression for analysing that result. Moreover, experiment has shown that observed ratios often deviate from statistical proportions because of fractionation factors (i.e. isotope effects that preferentially partition the heavier isotope into one chemical form versus another). The mathematical analysis for doubly labelled water studies, which includes the effects of fractionation factors, is well documented elsewhere.

Accelerator Mass Spectrometry

The sensitivity of tracer experiments increases as the naturally occurring isotopic background decreases. The natural abundance of ^{14}C in the biosphere (standardized to the year 1950) is approximately 1.2 parts per trillion (a

level designated as Modern), a factor of 10^{-10} lower than the natural abundance of ^{13}C . Moreover, when an organism dies, it ceases to equilibrate with atmospheric CO_2 and its ^{14}C decays away. Many commercially available compounds are petroleum derived and routinely contain ^{14}C levels $<1\%$ Modern. Therefore, mass spectrometric determination of ^{14}C has much greater sensitivity for tracer experiments than ^{13}C , with a usable detection limit of 0.001 fmole for ^{14}C versus 0.25 fmole for ^{13}C .

Accelerator mass spectrometry (AMS) is designed to analyse unstable isotopes, and a greatly simplified schematic is drawn in **Figure 2**. Historically, AMS measurements of isotopic ratios have been employed to measure half-lives of radionuclides by monitoring the disappearance of an unstable nuclide relative to a stable one (e.g. ^{44}Ti relative to ^{46}Ti) over a period of months. Contemporary applications address more chemical problems. The general technique involves two stages of ionization alternating with two stages of m/z selection. In the first ionization, atomic negative ions are produced from a solid sample, and the first mass spectrometer selects all ions with a given nominal mass. The negative ion is then accelerated to high velocity and transmitted through a foil stripper (a thin sheet of solid material), a passage that removes the outer electrons from the projectile ions. This second stage of ionization converts atomic ions with a single negative charge into positive ions with multiple charges, which are analysed by a second mass spectrometer.

When applied to ^{14}C , AMS makes use of a sample that has been converted to graphite. Since all chemical elements are present in the sample in concentrations greater than one part in 10^{12} , a major obstacle is to avoid

isobaric ions. Bombarding the graphite with a fast ion beam produces C^- among the stable atomic ions. Nitrogen atoms do not form stable negative ions, so the only atomic negative ion produced having m/z 14 is $^{14}\text{C}^-$. Along with this are produced a number of isobaric m/z 14 molecular ions, such as $^{13}\text{CH}^-$ and $^{12}\text{CH}_2^-$. The m/z 14 negative ions are mass selected by a low-energy mass spectrometer. The ion beam is then accelerated to megavolt kinetic energies and passed through a thin carbon foil, which strips off all the valence electrons. The molecular ions fragment as a consequence, while the atomic carbon ions simply acquire up to six positive charges. The mass filtering of AMS relies upon selection of m/z 3.5 positive ions ($^{14}\text{C}^{4+}$) formed from previously selected m/z 14 negative ions. One might think that two stages of mass analysis would suffice to separate the ^{14}C atomic ions from all other isobars, but there is a substantial interference from $^7\text{Li}_2^-$ in the source that is converted to $^7\text{Li}_2^{2+}$ by passage through the foil stripper. Therefore, the final stage of identification of ^{14}C requires that the ion beam be velocity selected and then passed through an ionization chamber, where collisions with neutral gas molecules produce secondary ions with a rate that distinguishes between a doubly charged projectile ($^7\text{Li}_2^{2+}$) and a quadruply charged projectile ($^{14}\text{C}^{4+}$). The high kinetic energy of the ions in AMS permits sensitive single-ion counting, and samples containing $<10^6$ atoms of ^{14}C in <1 mg total carbon can routinely be analysed.

In practice AMS is used to measure $^{14}\text{C}/^{13}\text{C}$ isotopic ratios. For most applications the variation of ^{13}C abundance in the sample does not significantly affect the accuracy of an AMS measurement. AMS has been widely used for samples whose ^{14}C content is below Modern (as in carbon dating) and is beginning to find major

Figure 2 Schematic of the accelerator mass spectrometer at the Centre for AMS at Lawrence Livermore National Laboratory. Negative ions from a multi-sample ion source are separated by a low-energy mass spectrometer, accelerated to 6 MeV in an electrostatic accelerator, converted to positive ions by passage through a foil stripper, and accelerated again. Quadruply charged carbon atomic ions (30 MeV kinetic energy) are focused by quadrupole lenses and resolved by high-energy mass spectrometers, followed by velocity selection and identification of charge state in an ionization detector.

applications for samples where ^{14}C content greatly exceeds Modern (as in biomedical research). The latter is exemplified by a study of covalent modification of proteins. When the enzyme aldolase is treated with acetoacetic ester, the protein irreversibly attaches a small but reproducible amount of the ester. Such a low level of tagging is sometimes referred to as background labelling, since (even with carrier-free (^{14}C)acetoacetic ester) there is not enough incorporated radioactivity to give a decay rate very much higher than the background for detecting nuclear disintegrations. The isotopic label stands out well above natural ^{14}C levels, but decay counting is an intrinsically inefficient method of detection. No matter what type of counter is used, only fourteen ^{14}C nuclei will decay per hour for every 10^9 that are present in the sample. In the case of tagged aldolase, the amount of incorporated radioactivity was too low for decay counting to be used for fragments of the tagged enzyme, and AMS presented the only method for analysing ^{14}C content after cleavage of the protein.

AMS takes advantage of the inherent efficiency of mass spectrometry and can readily measure the amount of label in protein fragments purified by analytical gel electrophoresis. Site-specific chemical cleavage of tagged aldolase gave four electrophoresis bands, each containing ≤ 0.05 mg of polypeptide. Individual gel slices (containing 5–10 mg of polyacrylamide each) were converted to CO_2 and then reduced to pure graphite. AMS gave analyses that showed $^{14}\text{C}/^{13}\text{C}$ ratios in the range from 5 to 50 times Modern reproducibility, depending on the identity and quantity of labelled polypeptide in the gel slice, which (when corrected for the great excess of stable carbon isotopes contributed by the polyacrylamide) corresponded to $0.03\text{--}3$ fmol ^{14}C per polypeptide fraction. The extent of labelling was found to be nonuniform: it did not correlate with the molecular mass of the fragments but was proportional to the number of tyrosine residues. No correlation was observed for any other amino acid. Therefore, what had hitherto been dismissed as background labelling turns out to be an amino acid-specific covalent modification.

Tracer Studies for Characterizing Reaction Pathways

Mass spectrometry is typically used to look at products from reactions where a reactant has intentionally been enriched in a rare stable isotope. This is illustrated by a 'crossover experiment' reported by P.D. Bartlett and T.G. Traylor in 1963, who reported the labelling of molecular oxygen liberated by chain termination of free *t*-butyl hydroperoxy radicals. When a radical doubly labelled with ^{18}O reacted with an unlabelled radical to yield di-*t*-butyl peroxide (eqn [4]), the predominant gaseous

product gave m/z 34 ($^{16}\text{O}^{18}\text{O}$). That outcome indicates that each radical contributes one oxygen atom and implicates a tetroxide intermediate, which could not be directly observed.

An experiment that fails to show crossover can be equally meaningful. The 1953 report by F.A. Loewus, F.H. Westheimer and B. Vennesland on the enzyme alcohol dehydrogenase represents one of the earliest and most profound applications of isotopic labelling. These experiments demonstrated the facial selectivity of the enzyme-catalysed reaction, which is depicted schematically in eqn [5]. They performed mass spectrometric analyses of mixtures of HD and H_2 produced by reduction of water from combusted samples of ethanol and acetaldehyde, and they established that the (*R*) enantiomer of deuterated ethanol transfers only deuterium to the coenzyme NAD^+ (a partial structure of which is drawn in eqn [5]). The reduced coenzyme transfers only deuterium back to acetaldehyde. Under conditions where the reaction goes back and forth many times, no deuterated acetaldehyde ($\text{CH}_3\text{CD}=\text{O}$) is detected. If, on the other hand, $\text{CH}_3\text{CD}=\text{O}$ reacts with the unlabelled, reduced coenzyme (known as NADH), the reduction gives (*S*)-1-deuterioethanol. No label transfers between deuterated acetaldehyde and the coenzyme. The remarkable conclusion (confirmed for many enzymes subsequently) is that biological catalysts distinguish the two faces of planar carbon atoms that bear three nonidentical substituents (e.g. the top and bottom faces of the planar ring of NAD^+ and of the carbonyl carbon of acetaldehyde).

MS/MS – Tandem versus Ion Storage

In the gas phase, a neutral molecule can be ionized by removal or addition of an electron via an electron beam (electron ionization or EI), by reaction with another gaseous ion (chemical ionization or CI), or by interacting

with ionizing radiation. Most methods of depositing charge are so energetic that they lead to fragmentation. By close examination of fragment ions, one can sometimes draw conclusions regarding the placement of isotopic label and the mechanism of ionic decomposition. Quite often the source mass spectrum is confusing, since isotopic label frequently randomizes under typical ionization conditions. Sequential mass spectrometry separates a portion of the ion beam (usually a single nominal m/z) and reanalyses it after it has undergone subsequent ion decompositions. Two general types of MS/MS apparatus enjoy wide usage: those that have mass spectrometers in spatial sequence (tandem instruments) and those that examine ions using a single mass spectrometer, in which the two stages of mass selection occur in temporal sequence (ion storage instruments).

Ions that fragment between two stages of mass selection are said to undergo metastable ion decompositions. These often show patterns different from a source mass spectrum. The spectrum from which **Figure 1** is taken provides an example. Electron ionization of $C_6H_5OCH_2CD_2OH$ shows a $C_6H_7O^{*+}$: $C_6H_5DO^{*+}$: $C_6H_6DO^+$ ratio of about 0.75:1: 0.6. Metastable ion decomposition of the corresponding molecular ion $C_6H_5OCH_2CD_2OH^{*+}$ shows a ratio $<0.05:1:2$. The high-resolution spectrum in **Figure 1** required a two-sector instrument. In metastable studies, the same two sectors were used in tandem. Since isobaric m/z 95 ions cannot be resolved by a single sector, the $C_6H_7O^{*+}$: $C_6H_5DO^{*+}$ abundance ratio from metastable ion decompositions had to be inferred from a comparison of several additional isotopic variants, $C_6H_5OCH_2CD_2OD$, $C_6H_5OCD_2CH_2OH$, $C_6H_5OCD_2CD_2OD$ and $C_6D_5OCH_2CH_2OH$.

Determination of Isotopic Stereochemistry

In favourable cases, configuration of an isotopically substituted stereogenic centre can be determined by means of mass spectrometric fragmentation. The labelled analyte must contain a ring or else must pass through a cyclic transition state in the course of decomposition. Acyclic secondary alcohols with a single deuterium adjacent to the oxygen-bearing carbon (general formula $R^1CHOHCHDR^2$) have two diastereomeric forms as a consequence of isotopic substitution. While the mass spectra of the alcohols present major difficulties of interpretation, several derivatives undergo mass spectrometric eliminations by which relative stereochemistry can be assigned. The ionized phenyl ethers, for instance, expel neutral alkene. The $C_6H_5OD^{*+}$: $C_6H_5OH^{*+}$ ratios differ from one stereoisomer to the other to such an extent that ion storage techniques can be used to assay the proportions of isotopic diastereomers. While chromatography cannot separate isotopic isomers, GC-MS/MS for quantitating mixtures of isotopic diastereomers has been reduced to practice.

In 1979 Knowles, McLafferty and their co-workers made dramatic use of metastable ion mass spectrometry in solving the stereochemistry of phosphate monoesters $ROP^{16}O^{17}O^{18}O^{2-}$ that are chiral by virtue of substitution with oxygen isotopes. Reaction with optically active 1, 2-propanediol affords the mixture of three isotopomeric cyclic triesters shown to the left in **Scheme 2**. One $ROP^{16}O^{17}O^{18}O^{2-}$ enantiomer gives the mixture depicted; the other $ROP^{16}O^{17}O^{18}O^{2-}$ enantiomer gives products in which ^{17}O and ^{18}O are transposed. Ring opening with methanol gives a mixture of three isotopomeric triesters (middle of **Scheme 2**) that exhibits mass spectrometric

Scheme 2

fragment ions corresponding to trimethyl phosphate. The isotopomeric trimethyl phosphate radical ions display prominent metastable ion decompositions from loss of formaldehyde. For one $\text{ROP}^{16}\text{O}^{17}\text{O}^{18}\text{O}^{2-}$ enantiomer the m/z 142 fragment loses only CH_2^{16}O , as **Scheme 2** portrays, while m/z 141 loses either CH_2^{16}O or CH_2^{17}O and m/z 143 loses either CH_2^{16}O or CH_2^{18}O . These metastable ion decompositions are summarized beneath their respective trimethylphosphate ions to the right in **Scheme 2**. The other $\text{ROP}^{16}\text{O}^{17}\text{O}^{18}\text{O}^{2-}$ enantiomer leads to ions (not shown in **Scheme 2**) for which m/z 141 loses only CH_2^{16}O ; m/z 142 loses CH_2^{16}O or CH_2^{18}O ; and m/z 143 loses CH_2^{16}O or CH_2^{17}O .

Elucidation of Fragmentation Pathways and Isotope Effects

Isotopic labelling provides an excellent method for probing how ions decompose in the mass spectrometer. Frequently the pathway followed by an ion resembles a cognate reaction from solution chemistry, but sometimes the outcome differs quite unexpectedly. Many elimination reactions – both in solution and in the gas phase – operate via loss of groups attached to adjacent atoms. But EI on $(\text{CH}_3)_2\text{CDCH}_2\text{CH}_2\text{Br}$ yields an $\text{M}-\text{DBr}$ daughter ion that is much more abundant than the $\text{M}-\text{HBr}$ fragment. The structure of the ion (inferred from subsequent surface neutralization and analysis of the C_5H_{10} neutral) is $(\text{CH}_3)_2\text{C}=\text{CHCH}_3$. Clearly some transposition of hydrogen has taken place. Investigating the rearrangements of gaseous ions represents a major area of research in mass spectrometry.

Deuterium substitution often affects the competition between two otherwise identical fragmentation pathways. EI on 1, 4-dimethoxybutane shows no molecular ion and an intense peak from loss of methyl radical (a fragmentation not seen in the shorter or longer homologous α,ω -dimethoxy- *n*-alkanes). When ionizing energy is lowered, the contribution from methyl loss increases until it represents >70% of the total ionization. Deuterating one methyl ($\text{CD}_3\text{OCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{OCH}_3$) exerts a comparatively small isotope effect: loss of CD_3 is 0.7 as intense as loss of CH_3 . Deuterating the nearest methylene as well ($\text{CD}_3\text{OCD}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{OCH}_3$) lowers the loss of CD_3 to 0.5 the intensity of loss of CH_3 . In other words, replacing two H atoms with D on the other side of the oxygen has as great an effect as replacing all three H atoms with D on the methyl itself. This has been taken to imply a hidden hydrogen rearrangement, in which a proton transfers to the remote oxygen simultaneously with a C–O bond cleavage.

If two reactions exhibit different isotope effects in a product-determining step, they cannot be proceeding via a common intermediate. For example, elimination of propene produces the most intense fragment ion in the EI and CI mass spectra of *n*-propyl phenyl ether, with extensive

scrambling of all of the hydrogens in the side-chain. Could it be that the *n*-propyl ether ions isomerize to isopropyl ether ions prior to dissociating? If so, photoionization of $\text{CD}_3\text{CH}_2\text{CH}_2\text{OPh}$ and $\text{CH}_3(\text{CD}_3)\text{CHOPh}$ should manifest the same isotope effects on propene expulsion. But the isotope effect (measured as the $\text{C}_6\text{H}_5\text{OH}^{+\bullet}/\text{C}_6\text{H}_5\text{OD}^{+\bullet}$ intensity ratio) is about 1.2 for *n*-propyl, significantly less than the value (1.4) for isopropyl. Therefore, the two isomeric ions dissociate via distinct pathways.

Discrimination of Isobars and Isomers

Isotopic labelling often shifts the mass of one isobar relative to another for the purposes of identification. In ionized mixtures of methyl fluoride with a trace of ammonia, the weakly hydrogen-bonded cluster ion $\text{CH}_3\text{F}-\text{H}\text{NH}_3^+$ (m/z 52) has the same mass as a much more stable ammonia cluster ion, $(\text{NH}_3)_3\text{H}^+$. With $^{15}\text{NH}_3$ the mass-to-charge ratios become m/z 53 and m/z 55, respectively. Moreover, the isotopic substitution identifies the product of the m/z 52 $\rightarrow$ m/z 53 fragmentation as FCH_2^+ .

Ion structures can be deduced from isotopic labelling. One of the first distonic ions ever demonstrated, portrayed in eqn [6],

was characterized by its reaction with gaseous base to transfer only D^+ . If the ion had had the ionized methyl ether structure, it would have transferred H^+ at least as often as D^+ . A similar type of experiment demonstrated that the distonic ion in eqn [7] converts to (or interconverts with) ionized methoxycyclopropane, since the two isotopomers [4] and [5] transfer H^+ and D^+ to gaseous bases in the same proportions.

Nuclear Magnetic Resonance and Mass Spectrometry

Neutral products from decomposition of gaseous ions can be isolated and subsequently characterized by gas chromatography or magnetic resonance spectroscopy. Fluorine

Figure 3 ^{19}F NMR spectra (proton noise-decoupled) of deuterated fluoroethylenes expelled from the indicated dideuterated β -fluorophenetoles after 70 eV electron ionization. Observed peak splittings come from deuterium–fluorine spin–spin coupling, by which isomers/isotopomers are identified. Reproduced with permission of the American Chemical Society from Nguyen V, Cheng X, and Morton TH (1992) *Journal of the American Chemical Society* 114: 7127.

NMR has been especially useful in this regard, since the ^{19}F chemical shift scale is so wide that isotopic shifts of NMR peak positions permit assessment of the extents and positions of deuteration in isomers/isotopomer mixtures.

Figure 3 reproduces ^{19}F NMR spectra of fluoroethylenes recovered from EI of two different isomers of dideuterated β -fluorophenetole. The isomers give slightly different mass spectrometric fragmentation patterns, but the decomposition mechanism could not be fully understood without the analysis of the expelled neutrals. As the NMR shows, the distribution of deuterated fluoroethylenes is not the same for the two isomers. One isomer yields a product not formed by the other, and vice versa. $\text{C}_6\text{H}_5\text{OCH}_2\text{CD}_2\text{F}$ produces $\text{CHD}=\text{CHF}$, but $\text{C}_6\text{H}_5\text{OCH}_2\text{CD}_2\text{F}$ does not. $\text{C}_6\text{H}_5\text{OCH}_2\text{CD}_2\text{F}$ produces $\text{CHD}=\text{CDF}$, but $\text{C}_6\text{H}_5\text{OCD}_2\text{CH}_2\text{F}$ does not. Hence hydrogens cannot be randomizing within ionized β -fluorophenetole prior to elimination.

It turns out that ionized β -fluorophenetole dissociates via two competing pathways, illustrated in eqn [8], which are indistinguishable but for the isotopic label. Both involve cleavage of the sp^3 -carbon oxygen bond to form ion–neutral complexes, which exist for the order of a nanosecond before a proton transfers from the fluorine-containing cation to the phenoxy radical. The upper pathway drawn in eqn [8] has the fluorine bridging between two carbons, yielding a symmetrical cation structure. The lower pathway involves a hydrogen shift to form the most stable of the possible $\text{C}_2\text{H}_5\text{F}^+$ structures. The two competing mechanisms operate in about a 1:2 ratio.

Chemists have long dreamed of combining mass spectrometry with NMR, so as to probe the structures of gaseous ions directly. Recent commercial introduction of combined NMR/MS instrumentation has been realized, primarily for applications to metabolomics/metabonomics analyses.

The elucidation of the pathways involved in the metabolism of exogenous and endogenous materials has been advanced considerably by the use of labelled chemicals. The transformation of these labelled intermediates can be followed by a variety of techniques. Much of the early work in the elucidation of pathways of intermediary metabolism involved the use of radioactive isotopes, and ^{14}C in particular, as tracers. More recently, the focus of research has been on the control of metabolism, and flux through pathways. Nuclear magnetic resonance (NMR) spectroscopy has been used in the study of metabolic processes to follow the conversion of compounds with natural abundance isotopes such as ^1H , ^{19}F , or ^{31}P or isotopically labelled compounds containing ^2H , ^{15}N , or ^{13}C . This discussion focuses on the application of isotope labels to track the fate of chemicals in biological systems. The majority of the NMR applications involving labels use ^{13}C -enriched chemicals and in general are designed to describe the pathways of metabolism or to evaluate flux through pathways. Although less frequently used, ^2H and ^{15}N can also provide useful information. An isotope effect on metabolism resulting from the increase in mass with ^2H compared with ^1H may be a significant limitation. ^{15}N labels are limited to the study of nitrogen-containing compounds and have generally been limited by the low sensitivity for detection of ^{15}N . Two types of applications can be identified: those in which the metabolism of endogenous materials is assessed by addition of labelled materials, with the fate of the label indicating the fate of the pool of both labelled and unlabelled material and those in which the metabolism of labelled exogenous materials is assessed.

Detection of ^{13}C -Labelled Metabolites

^1H NMR spectroscopy, which is widely used for structure elucidation, is very sensitive as a result of both the

high natural abundance and NMR sensitivity of the proton. As a means of tracking the fate of chemicals in biological systems, ^1H NMR is widely used and works well with chemicals with functional groups whose NMR signals can be distinguished readily from endogenous materials (see also other sections). However, ^1H NMR is, in general, not very selective, and frequently lacks the ability to discriminate among compounds of interest in complex biological mixtures. In addition, water in biological systems causes dynamic range issues that must be circumvented by suppression techniques during the acquisition of ^1H NMR spectra. Carbon-13 occurs with a low natural abundance (1.1%), and has a spin quantum number of $1/2$; ^{13}C has an NMR sensitivity 1.6% that of ^1H , but is highly selective. Signals in ^{13}C spectra are dispersed over a wide frequency range, depending on the substituents of the carbon atom from which the signal arises. The wide dispersion of ^{13}C NMR signals is one of the major reasons for using ^{13}C -enriched chemicals in the study of metabolism. Using ^{13}C -enriched materials permits detection over the low natural abundance of unlabelled materials. Compared with natural abundance of 1.1%, enrichment of a carbon atom to 99% would cause an increase in the signal-to-noise ratio of 90-fold. The use of NMR for the detection of labelled materials has the advantage over other techniques that the enrichment at a particular carbon atom in a molecule can readily be determined without degradation of the molecule.

Proton-decoupled ^{13}C NMR signals for natural abundance materials occur as singlets since the probability of two adjacent ^{13}C nuclei is 0.0123%. An isolated enriched carbon atom in an otherwise natural abundance material gives rise to a single resonance. Adjacent enriched carbon atoms give multiplet patterns as a result of carbon-carbon coupling. Two adjacent ^{13}C atoms each give rise to a doublet as shown in **Figure 1**. The NMR

Figure 1 Diagrammatic representation of ^{13}C NMR spectra illustrating carbon-carbon coupling. (a) The spectrum of two connected natural abundance carbon atoms. (b) The spectrum of two directly connected ^{13}C atoms. The separation between each doublet is equal to the carbon-carbon coupling constant (J_{CC}). (c) The spectrum of three directly connected ^{13}C atoms.

spectrum of three adjacent ^{13}C atoms ($\text{C}_a\text{--C}_b\text{--C}_c$) will give rise to a doublet for each of the external carbons (C_a and C_c) and a doublet of doublets for the centre carbon atom (C_b), excluding the effects of long-range $^{13}\text{C}\text{--}^{13}\text{C}$ coupling. This type of splitting pattern permits the distinction of exogenous and endogenous compounds. In mixtures, a singly labelled compound may not readily be distinguished from endogenous signals, whereas the multiplet patterns associated with multiply labelled materials readily stand out.

The ^1H -decoupled 1D ^{13}C NMR spectrum is the general starting place for the detection of labelled metabolic intermediates or products. In the study of intermediary metabolism, assignments can frequently be made by comparison of the chemical shifts of signals with those from known standards. With multiply labelled metabolites, more detailed structural information can be obtained by the acquisition of additional spectral information. The measurements of carbon-carbon coupling constants from the 1D spectrum may be used to determine the connection between carbon resonances. In mixtures, however, coupling patterns for carbon atoms from different compounds can be similar. Carbon-carbon connectivity experiments (e.g. incredible natural abundance double quantum transfer experiment; INADEQUATE) provide an unambiguous determination of carbon-carbon connectivity. The two-dimensional spectra generated from these experiments contain a dimension for chemical shift and a dimension for double quantum frequency. The presence of two contours with the same double quantum frequency (i.e. aligned horizontally along the F_1 axis) but with different chemical shifts (F_2 axis) indicates coupling between the carbons giving rise to these signals (**Figure 2**). These experiments can be conducted to determine direct and long-range carbon-carbon coupling.

Figure 2 Diagrammatic representation of an INADEQUATE spectrum illustrating carbon-carbon coupling.

Figure 3 Diagrammatic representation of a HET2DJ spectrum illustrating one-bond carbon-proton coupling.

A number of techniques permit the detection of the number of protons attached to specific carbon atoms. The attached proton test (APT) experiment and related pulse sequences can be used to distinguish between CH, CH_2 , and CH_3 carbon signals. However, they are not always able to distinguish between CH and CH_3 groups. The 2D carbon proton experiment (e.g. heteronuclear 2D J -resolved or HET2DJ) permits the identification of the number of hydrogen atoms attached to each carbon atom. The 2D spectrum generated from these pulse sequences contains a dimension for carbon chemical shift and a dimension indicating the multiplets produced by the attached protons ($2nI + 1$ rule). Carbons with three, two, or one attached protons will have four, three, or two contour peaks, respectively, aligned at the chemical shift of the carbon signal in the 2D spectrum (**Figure 3**).

Two-dimensional $^{13}\text{C}\text{--}^1\text{H}$ heteronuclear shift correlation allows the detection of the proton signals associated

with the labelled carbon atoms. Indirect detection methods are heteronuclear techniques with detection of the nucleus with higher gyromagnetic ratio. Detection of carbon signals through attached protons provides a considerable increase in sensitivity over that obtained in the 1D ^1H -decoupled ^{13}C spectrum. For biological samples, the increase in sensitivity can be outweighed by other factors, as described by Gemmecker and Kessler. In a complex mixture, for example, a large number of increments (second dimension of a 2D experiment) are required to obtain sufficient resolution of carbon cross peaks to allow the identification of the carbon chemical shift. This problem is alleviated by the use of computational techniques, such as linear prediction, by which smaller numbers of increments can be tolerated. Also, water suppression techniques must be employed with biological samples.

The chemical shifts of carbon atoms in various environments can be estimated through the use of substituent increments that have been tabulated over many years. Computational programs are also available, some of which use the same logic in the estimation of shift. In addition, database programs can be used to search existing spectral data and to calculate chemical shifts by interpolating from compounds in the database.

In the investigation of intermediary metabolism, the position of labelling in a newly synthesized molecule provides important information about the pathway of its formation. The potential labelling possibilities and the impact that these will have on the NMR spectra need to be considered. For a molecule with N carbon atoms, the number of carbon isotopomers (isomers with differing distributions of ^{13}C and ^{12}C) is 2^N . In biochemical studies, the potential number of isotopomers possible may not be realized. However, even a small number of possibilities can add considerably to the complexity of the signals detected. For many studies, critical information is extracted from the analysis of isotopomer distribution by NMR and requires the interpretation of complex signals for individual metabolites. Frequently computer simulation of the expected spectra is conducted to enable interpretation.

Detection of Other Labels

Deuterium-labelled materials are readily available and can be applied to studying metabolic processes. However, ^2H has a spin quantum number of 1 and is relatively insensitive compared with ^1H (9.7×10^{-3}). It has a low natural abundance of 0.016%.

Of the two isotopes of nitrogen, ^{15}N with a spin quantum number of $1/2$ is the most widely used. It is very insensitive (1×10^{-3}), and has a low natural abundance of 0.37%. While some studies have used the direct detection of ^{15}N -labelled compounds, the indirect

detection of ^{15}N through ^1H by techniques such as INEPT (insensitive nuclei enhanced by polarization transfer) and inverse detection schemes such as ^1H - ^{15}N HMQC and HSQC (heteronuclear multiple quantum coherence and single quantum coherence respectively), which considerably enhance sensitivity, has increased the applicability of ^{15}N in biological systems.

Applications of Labels

Exogenous Metabolites

^{13}C -labelled tracers have been used in the elucidation of the pathways of metabolism of a number of exogenous chemicals, with labels incorporated in one or several carbon atoms of the materials of interest. The metabolism of ^{13}C -labelled formaldehyde, a chemical with a single labelled carbon, provides an uncomplicated illustration of the use of a labelled material in the study of metabolism. The metabolism of formaldehyde to formate, methanol, and several additional metabolites could be determined from the 1D ^1H -decoupled ^{13}C spectrum of *Escherichia coli* incubated with ^{13}C -labelled formaldehyde (Figure 4). From ^1H -coupled spectra, two of these metabolites with signals at 64 and 68 ppm appeared to contain labelled carbons present as CH_2 groups. ^{13}C - ^1H correlation spectra indicated that these additional metabolites contained protons in the range 3.4–3.7 ppm, with nonequivalent protons on each labelled carbon atom. The metabolism of formaldehyde to produce 1,2-propanediol, 1,3-propanediol, and glycerol was established by culturing *E. coli* in medium containing 14.3% uniformly labelled ^{13}C -glucose, administering 90% labelled ^{13}C -formaldehyde, and analysing the products formed by ^{13}C NMR spectroscopy. The ^{13}C - ^{13}C couplings produced permitted the detection of the signals from the glucose-derived carbon atoms adjacent to the formaldehyde-derived carbons. An additional metabolite was determined to be S - ^{13}C -hydroxymethylglutathione, formed by addition of ^{13}C -labelled formaldehyde to glutathione.

^{13}C -labelled materials have been used in the elucidation of pathways of metabolism of many chemicals. Information can be obtained from chemicals containing more than one carbon atom but only a single labelled carbon. Following administration of $[3\text{-}^{13}\text{C}]\text{-1,2-dibromo-3-chloropropane}$ (81 mg kg^{-1}) to rats, 15 biliary metabolites and 12 urinary metabolites were observed. Metabolites were assigned based on chemical shift, proton multiplicity, ^{13}C - ^1H correlation spectra, and comparison with synthetic standards. The metabolic profile proposed for this material is shown in Figure 5.

The incorporation of multiple labels into a compound with multiple carbon atoms provides an opportunity for using additional methods for characterizing metabolites. Following administration of $[1,2,3\text{-}^{13}\text{C}]\text{-acrylonitrile}$ to

rats and mice, a number of metabolites in urine were detected and assigned structures based on chemical shift, carbon–carbon multiplicity, carbon–carbon connectivity, and proton multiplicity. Examples of the spectra obtained in urine from rats administered [$1,2,3\text{-}^{13}\text{C}$]acrylonitrile are shown in **Figure 6**. The multiplets assigned to the labelled carbons of the metabolites result from carbon–carbon coupling (**Figure 6c**). The HET2DJ spectrum

shown in **Figure 7** illustrates the determination of the number of protons attached to each labelled carbon atom. The HET2DJ spectra obtained from multiply labelled compounds provide an additional means of distinguishing signals derived from labelled compounds from natural abundance carbon signals in that the carbon–carbon coupling displaces the multiplets from the centre of the F_1 axis. For example, each peak of the doublet labelled 3a

Figure 6 The ^1H -decoupled ^{13}C NMR spectrum of (a) control rat urine and urine collected for 24 h following administration of (b) 10 or (c) 30 mg kg^{-1} $[1,2,3\text{-}^{13}\text{C}]$ acrylonitrile. Signals are labelled according to metabolite number (see **Figure 8**, and the letter of carbon-derived from acrylonitrile (${}_a\text{CH}_2\text{=}_b\text{CH}_2\text{-}_c\text{CN}$)). Reprinted with permission from Fennell TR, Kedderis GL, and Sumner SC (1991) Urinary metabolites of $[1,2,3\text{-}^{13}\text{C}]$ acrylonitrile in rats and mice detected by ^{13}C nuclear magnetic resonance spectroscopy. *Chemical Research in Toxicology* 4: 678–687. Copyright 1991, American Chemical Society.

(**Figure 7**) has three contours aligned along the x -axis, indicating that the signals are from a labelled methylene carbon. The nature of the labelled carbon atoms in metabolites derived from acrylonitrile could be assigned. The identity of the unlabelled substituents of the metabolites could be inferred from the substituent effects on the chemical shifts of the labelled carbons. Most of the metabolites detected were derived from conjugation of

acrylonitrile or its epoxide metabolite, cyanoethylene oxide, with glutathione and further metabolism of the glutathione-derived portion of the metabolites. The metabolism of acrylonitrile concluded from this study is shown in **Figure 8**. Quantitation of metabolites was conducted with dioxane added as an internal standard by measuring peak areas under conditions that ensured adequate relaxation of the carbon signals of interest. This

combination of techniques has been used to study the metabolism of a number of compounds.

The metabolism of mixtures has received little attention, in part because of the complexity of the problem. NMR spectroscopy with labelled materials provides an ideal tool for studying the metabolism of several components of a mixture. On coadministration of [1,2,3- ^{13}C]acrylonitrile and [1,2,3- ^{13}C]acrylamide to rats and mice, the metabolites of both compounds could be resolved readily in the urine.

Endogenous Metabolites

NMR spectroscopy has been widely used in the investigation of metabolism. Therefore, only a very general review of this area can be provided. For additional information, the reader is directed to the references contained in the Further Reading section. Most of the recently reported studies involve investigation of the regulation of metabolism. Generally, one or more labelled starting materials are administered in a biological system: subcellular fractions, cells, isolated perfused organs, or whole animals. NMR spectroscopy has been applied to the investigation of metabolism in a wide range of experimental systems from plants to animals and people. Analysis can be conducted at the level of cell extracts, whole cells, body fluids, whole tissues, and *in vivo*. Mammalian tissues that are widely studied include brain, liver, muscle, and heart. The use of multiply labelled compounds aids in distinguishing high levels of naturally occurring unlabelled materials (which give

singlet signals) from low levels of added labelled material (which yield multiplet signals) and can provide a means for distinguishing added from endogenous material in determining the size of pools by reverse isotope dilution.

Many pathways of metabolism have been studied using labelled chemicals, including the conversion of glucose to glycogen, glycolysis, the Krebs cycle, fatty acid metabolism, amino acid metabolism, and the pentose phosphate pathway. Among the considerations in conducting studies involving the use of labels in metabolism is the introduction of the label into the biological system, the concentration of label required, distinction of pathways, and isotopomer distribution. Some of these issues can be illustrated with consideration of specific examples.

Oxaloacetate, malate, fumarate, and α -ketoglutarate are intermediates in the Krebs cycle that are present in very low concentration and are generally not directly detectable by NMR spectroscopy. Measurement of surrogates that accumulate to measurable levels such as glutamate, alanine, aspartate, and lactate is used for the determination of isotope distribution. Oxaloacetate, malate, and fumarate exist virtually in equilibrium. Glutamate and α -ketoglutarate are in fast equilibrium via transamination. Determination of the labelling pattern in glutamate is thought to be reflective of that of α -ketoglutarate and, in turn, of oxaloacetate. Similarly, aspartate and oxaloacetate are in equilibrium by transamination, and the labelling pattern of aspartate is thought to reflect that of oxaloacetate.

Succinate and fumarate are symmetrical molecules, and any label that passes through these intermediates can become scrambled. Introduction of a label from α -ketoglutarate into succinate (**Figure 9**) would result in the presence of the label at more than one site in a molecule. Such mixing can be indicative that the label has passed through a symmetrical intermediate.

Quantitative information can be obtained from isotopomer analysis in one of several ways: modelling with differential equations, modelling with infinite convergent series, and modelling with input-output equations (see the review by Künneke). Simplified models that focus on a limited number of isotopomers can be used to estimate the contribution of competing pathways.

The incorporation of $[1-^{13}\text{C}]$ glucose into glycogen can be followed by NMR spectroscopy. Glucose and glycogen give prominent signals in the natural abundance ^{13}C NMR spectrum of liver. The C-1 carbon signal of glycogen at 100.4 ppm can be readily distinguished from the C-1 signals of α - and β -glucose at 92.6 and 96.7 ppm. Although glycogen is a high molecular mass (10^9) molecule with extensive branching, the resonances of glycogen can be readily detected. The internal motion of the glucopyranose residues of glycogen is thought to be virtually unrestricted resulting in the observation of narrow line widths for glycogen signals. The

Figure 9 An illustration of the scrambling of a label by passage through the symmetrical intermediate succinate. Incorporation of ^{13}C in the 4-position of α -ketoglutarate results in the formation of $[2-^{13}\text{C}]\text{succinate}$, and in turn $[2-^{13}\text{C}]$ - and $[3-^{13}\text{C}]\text{oxaloacetate}$. Since no molecules labelled at both the 2- and 3-position would be produced, no coupling would be observed between the resonances.

incorporation of glucose into glycogen can take place by several routes, and not just by the direct conversion of glucose $\rightarrow$ glucose 6-phosphate $\rightarrow$ glucose 1-phosphate $\rightarrow$ UDP glucose $\rightarrow$ glycogen. Additional pathways involving the conversion of glucose $\rightarrow$ C_3 units $\rightarrow$ glucose 6-phosphate $\rightarrow$ glycogen had been extensively studied by NMR spectroscopy. Injection of $[1,2-^{13}\text{C}]\text{glucose}$ into fed rats resulted in the formation of liver glycogen labelled at both the C-1 and C-2 carbons, with spin-spin coupling (**Figure 10**). In fasted rats, the additional presence of the label at C-5 and C-6 indicates the synthesis of glycogen from newly formed glucose. The absence of $1-^{13}\text{C}$ - and $1,3-^{13}\text{C}$ -isotopomers ruled out the involvement of the pentose phosphate pathway in the synthesis of glucose. In the indirect pathway for glycogen synthesis, glucose is converted in several steps to dihydroxyacetone phosphate, which is rapidly isomerized to glyceraldehyde 3-phosphate. Glyceraldehyde 3-phosphate, in turn, can be used for gluconeogenesis via fructose 6-phosphate or via pyruvate and oxaloacetate. In either eventuality, the ^{13}C labels can appear simultaneously at the 5- and 6-positions of glucose in glycogen, giving rise to $[1,2-^{13}\text{C}]$ -, $[5,6-^{13}\text{C}]$ -, and $[1,2,5,6-^{13}\text{C}]\text{glucose}$.

Areas of Development

The use of indirect detection methods for the analysis of labels in biological systems has become more widespread. Examples of the application of these techniques can be

Figure 10 High-resolution ^{13}C NMR spectra (100.16 MHz) of enzymatically hydrolysed liver glycogen. Extracted and hydrolysed liver glycogen of (a) a fed and (b) a fasted rat after injection of $[1,2-^{13}\text{C}_2]\text{glucose}$. Reprinted with permission from Künnecke B and Seelig J (1991). Glycogen metabolism as detected by *in vivo* and *in vitro* ^{13}C -NMR spectroscopy using $[1,2-^{13}\text{C}_2]\text{glucose}$ as substrate. *Biochimica et Biophysica Acta* 1095: 103–113. Copyright 1991, Elsevier Science.

found in the literature. Metabolites of $[1-^{13}\text{C}]\text{glucose}$ have been detected in maize root tips using heteronuclear multiple quantum coherence (HMQC) NMR. Labelling of the amide group of glutamine could be detected by $^1\text{H}-^{15}\text{N}$ HMQC in root tips labelled with $^{15}\text{NH}_4^+$. Following infusion of $^{15}\text{NH}_4^+$, $^1\text{H}-^{15}\text{N}$ HMQC NMR has been applied to the detection of $[5-^{15}\text{N}]\text{glutamine}$ protons in rat brain.

Compounds labelled with stable isotopes, mainly ^2H and ^{13}C , have now been widely used in drug metabolism and toxicology studies to gain better understanding of drug disposition and xenobiotic-induced target organ toxicity. In addition, the combination of mass spectrometry and NMR spectroscopy has resulted in wider use of stable isotope-labelled compounds in absorption,

distribution, metabolism and excretion studies. Many examples also exist in plant science for the analysis of metabolic pathways and fluxes.

Laboratory Information Management Systems (LIMS)

Antony J Williams, ChemZoo Inc., Wake Forest, NC, USA

© 2010 Elsevier Ltd. All rights reserved.

Introduction

Modern laboratories providing analytical chemistry support have shifted from a staff of skilled experts acquiring and analyzing data just a few years ago to these staff dedicating a significant proportion of their time to the support and maintenance of open access or walk-up analytical instrumentation serving their user community. Organizations retain scientific expertise to be applied to the most challenging analyses, but rudimentary data acquisition and analysis is now in the hands of the general chemist. The need for Laboratory Information Management Systems (LIMS) has expanded from systems support for the processing of samples and requests in order to produce large numbers of test results and reports. Now LIMS have been expanded to support high-throughput generic and reproducible experiments for instrumentation with low downtime thus producing data outputs that will either provide canned paper reports or flow as data streams to the desktops of the chemists for processing and reporting. Today's laboratory workers are expected to be proficient in the utilization of highly automated spectrometer systems and their associated offline data processing suites and electronic notebooks for both data and knowledge management software. Analytical laboratories by default have had to computerize their sample tracking, tests, and results, especially in the Life Sciences industries where traceability for data is a necessary component of compliance. With this information accessible via a computer there are many benefits including methods management, test results, archive, calculation, comparison against specifications, control charting, and verification of instrument performance. The information is valuable for reference, problem solving, and modeling. While the management of complex spectroscopic data resulting from a heterogeneous environment of instrument types and vendors is hampered by a lack of standards and cooperation between instrument vendors and software developers, many companies at this point have successfully deployed analytical data management systems utilizing vendor software application programming interfaces. This allows them to query information contained within proprietary data formats and to build customized interfaces and data manipulation software. As the world has embraced the benefits of an Internet-based culture, the dramatic technical advances in the speed of data flow, the potential of data storage of enormous quantities of data, and the availability of flexible and intuitive desktop and

Web-based user interfaces enable chemists to process, analyze, and increasingly integrate their data into electronic notebooks. Software platforms for integrated analytical sciences, specifically spectroscopy and chromatography, chemical structure handling software, and information systems are now the norm.

The Product of an Analytical Laboratory

The main products of an analytical laboratory are data and information. Some of this information is in the form of new analytical techniques or methods that extend a laboratory's ability to characterize new materials. Many laboratory settings today also act as hosts for 'walk-up' or 'open access' systems and have responsibility for the everyday operations of the hardware and software components of these systems the delivery of data to the desktops of the users, the training of users in the manipulation and interpretation of experimental data. These individual operations may be labeled as 'service' and 'support' roles where in the former case a laboratory acquires and interprets data while in the latter it is more responsible for providing an environment for data acquisition to the users.

In either case these measurements are the key to understanding and controlling either research or manufacturing processes, solving development and manufacturing problems, and developing novel materials. Preparing samples, making measurements, analyzing data, and generating reports are the common processes analytical laboratories, acting in a service role, use to generate information. Complex instrumentation has continued to become highly automated, and menu-driven interfaces allow access to measurements available only to skilled analytical scientists just a few years ago. The development of novel analytical techniques commonly migrates from the hands of skilled researchers to the general chemist very quickly as organizations are forced to improve productivity and the quality of their measurements. Analytical laboratories can now produce many terabytes of data in just a few days, and so data are generated in isolation from the analytical scientists; whose responsibility is now focused on studying the most problematic samples, ensuring the uptime, maintenance, and throughput of the instruments, and working with the IT group to ensure delivery of the data, selection and training in the processing software, and a higher level of general support. Properly managing this process and

tracking the flow of work through the laboratory is critical to the efficient operation of a laboratory.

Analytical chemists and information specialists working to improve their own operations were the first to develop LIMS. They typically supported only one technique or small unit of a laboratory and did not communicate with other information systems. Over the years there have been dozens of LIMS vendors providing packages with varied capabilities and these have continued to adapt to keep up with the increasing demands for improved graphical user interfaces, ease of use, improved statistical analysis, and archival systems to name just a few standard selection criteria. Since 1993, the American Society for Testing and Materials has published a number of standard guides for anyone interested in LIMS, including users, developers, implementers, and laboratory managers. These guides define, appropriate to the time of release, standard terminology, a concept model, primary functions, an implementation guide, and a checklist. LIMS vendors have become experts in knowledge management and the provision of flexible software architectures to deliver a solution to meet the customers' needs rather than a solution that the customer must adjust their processes to.

Types of Laboratories

The information handling requirements of analytical laboratories vary from the research to manufacturing environments. A standard testing laboratory that supports manufacturing quality control and regulatory compliance uses analysis procedures that are well defined and strictly followed. These laboratories analyze relatively large numbers of samples and produce numerical or tabular results based on specific methods and protocols. Spectral analysis is usually used in this environment to determine concentration or verify identification relative to known reference spectra. Historically, such approaches were limited generally to the comparison of optical spectra; there has been an expansion into the use of both nuclear magnetic resonance and mass spectrometry-based techniques, especially by the life sciences, for example in their profiling of the metabolome and examination of biomarkers. The software analysis components of such approaches are complex in nature but have been automated to a large extent.

In contrast, a research analytical laboratory supporting the discovery of new materials uses analysis procedures that are defined in the mind of the analyst. While the analyst may use analytical techniques that are well defined, the process he/she chooses to apply to a particular sample is not predetermined, but is developed in response to the questions that need to be answered. These laboratories analyze fewer numbers of samples and

regularly produce results that combine graphics and images with textual reports. In this environment, spectroscopy is also used to elucidate chemical structure and determine three-dimensional spatial relationships. The output of such studies can produce detailed mechanistic understanding, details of kinetics and any of a myriad of physical phenomena that can be exposed by modern spectroscopic techniques.

Other types of analytical laboratory environments vary between these two idealized cases. Process control environments model a fully automated standard testing laboratory. Development environments reflect the need to move research testing for understanding to standard testing for manufacturing. Problems arise when a LIMS vendor tries to sell one generalized solution, customized to fit all environments, and vendors have to deepen their understanding of an organization's knowledge management needs to supply a solution traversing all laboratories. Research laboratories, due to their diverse needs, remain a challenge in terms of delivering a LIMS solution, and only a few niche players with in-depth knowledge of spectral data handling have attempted to address the needs of spectroscopic data management in this environment. These include Advanced Chemistry Development (ACD/Labs), Thermo Fisher, and Waters.

Selecting a LIMS

Many factors drive analytical laboratories to implement LIMS. These include the need to demonstrate value, comply with detailed regulatory requirements, manage large amounts of samples and tests from automated analysis and screening systems, automate laboratory processes, improve accuracy, and deal with increased demands for efficiency and documentation. For successful implementation of a LIMS, it is important to know which factors are most important and where productivity will be impacted, both positively and negatively. While it may be appropriate to utilize a reengineering process to simplify a laboratory's workflow before implementing a LIMS, the majority of research laboratories require flexibility in their approach and may develop bespoke solutions rather than be constrained by a vendor's solution.

The installation of a LIMS is commonly a difficult and frustrating task for some laboratories. LIMS generally work best in laboratories where the operation is well understood and standardized and where the processes do not have to be changed to match the LIMS. This is generally not the case in research and development environments where microscopy and molecular spectroscopy laboratories usually reside. The need to manage images, various types of spectra, and chemical structures adds to the problem. The delivery of systems to manage

integrated sample, workflow, structure, and spectroscopic data has been assumed by only a small number of niche vendors. Managers may still have a hard time finding a system that will work for their operations and meet the expectations of users, and the business case for buy and customize versus build can be unclear.

Functions of a LIMS

Whether they support manufacturing, research, or problem solving, all analytical laboratories receive and prepare samples, make measurements, analyze data, and report results and information. A simplified illustration of the analytical support process is shown in **Figure 1**. Improving the overall efficiency of this process is the primary function of a LIMS. The most common and perhaps most important use of a LIMS is to maintain proper records on samples and the tests requested on them. This electronic logbook or sample management type function assigns sample numbers or bar codes and records administrative information, often including an indication of the work requested. Most LIMS also allow

numerical and tabular results to be entered for tests performed on the samples. Once data have been collected and properly recorded, the LIMS may be used for data manipulation and automated report generation. Significant productivity enhancements are usually obtained from this last step. The following sections describe how a LIMS is used to support the steps in **Figure 1**.

Definition of Problem or Job

For the laboratory supporting research, problem solving, or method development, the definition of a problem or job is the first step of the analysis process. Job requests could include determining what is happening to a material as it degrades, how the properties of a material might be improved, or if a fabrication process is producing devices with the desired composition and geometry. When a new chemical is to be commercialized, the request may be to develop tests and fitness-for-use criteria needed for production monitoring. The job usually defines the context for investigative analytical work performed on many samples. When the work is

Figure 1 Generic analytical laboratory workflow supported by LIMS.

complete and a report is written, this information may be made available in an electronic library.

In a standard testing laboratory, the problems or jobs are predefined by the time materials are analyzed. Given a type of material and its point-in-process, the suite of required tests, testing methods, specification limits, and resulting actions and reports are clearly defined.

Sample Login

A primary function of the LIMS is to track the samples of materials to be analyzed by a laboratory. This can be as simple as tracking when a sample enters and leaves a laboratory or as detailed as tracking every action that is performed on the sample while it is in the laboratory. The process normally begins with the client or analyst recording general descriptive information about each new sample or batch of samples and the work request. Typical information includes the name of the requester of the work, an account number to be charged for the work, the date the request is made, the client's identifier for the sample, the date the sample is received, the job or project to which this sample belongs, the priority, and the hazard information. Test requests vary from a general description of the problem to be solved to a suite of specific point-in-process tests using very specific methods.

Sample Receipt and Review

Samples may be logged into a LIMS before they arrive in the laboratory. Good-quality operating procedures dictate that when a sample arrives, it should be reviewed to ensure it is suitable for analysis, the requested work is appropriate, and it has not visually degraded. The LIMS sample receipt function allows the time a sample arrives and any anomalies to be recorded. If anomalies are observed in the sample, then a decision to proceed, resample, or request other tests is made, often after consultation with the client.

Test Assignment

The client may request a specific collection of tests when the sample is logged in. In a standard testing environment, the suite of tests is often assigned automatically by the LIMS. If a general test is requested or the request is for some problem to be solved or investigated, then the appropriate specific tests or course of investigation is selected by the analyst.

Allocation of Work

Work may be allocated among specific instruments, analysts, or support groups. This is done to match the test requirements to appropriately skilled analysts and equipment and ensure the best utilization of resources.

If samples are received in a laboratory with different priority levels, it can be accounted for here. When work is allocated, it is recorded in LIMS so that it can generate work lists for the analysis and instruments. In other cases, analysts simply check out the next pending sample from the queue in LIMS. In a research or problem-solving area, this may not be recorded in a LIMS until the results are entered.

Method Management

Methods are the procedures and protocols by which materials are analyzed. LIMS designed for standard testing laboratories often provide some support for managing methods. This can allow complete automation of the analytical process, as exemplified by online analysis.

Sample Preparation

Most samples and analysis techniques require some preparation such as dissolving, diluting, or mounting before measurements can be made. This step and the subsequent measurement step are a typical focus for laboratory automation using robotics. Such systems follow detailed procedures that may vary for every sample. Most automated sample preparation and measurement systems were initially isolated, performing very focused tasks and requiring manual data transfer at the beginning and end of a run. This has changed as automation and LIMS have matured and computer-controlled balances, integrated bar coding, and wireless transmission of measurements have developed.

Perform Measurements

Measurements are performed using instruments. In an automated laboratory, the LIMS can download data acquisition instructions to the instruments and receive data and analysis results for entry into its database. Nowadays LIMS utilize standard computer protocols to interface with instruments. This has been particularly successful in chromatography where good standards have been developed and followed by both LIMS and instrument vendors, but due to the explosive growth in hyphenated chromatography-mass spectrometry techniques, this integration has also been applied to LC-MS technology.

Result Entry

After the tests have been performed, the results are often entered into the LIMS. While this used to be primarily a manual process, generally data are now streamed directly into the LIMS or the raw data are moved into an archival system and a reduced form of the processed data is moved into the LIMS. These can be simple yes or no phrase results to tables of amounts of various materials.

Usually these tables have to be predefined by the method that is used to perform the analysis. Efforts in spectroscopy were previously limited partly by the lack of widely accepted standard spectral formats and partly by the lower demand for general spectroscopy applications in standard testing areas. As spectroscopic analyses have become crucial in the life sciences for genomics, proteomics, metabolomics, and metabonomics measurements, the results of analysis extracted from the raw data by complex software processing are assembled into tables and fed to a LIMS for review.

Calculations and Data Analysis

Most LIMS provide simple capabilities to perform calculation on the results that are entered. These calculations may simply be transformations into standard units or the generation of averages. More sophisticated analysis is generally performed using instrument vendor data systems or specialized data analysis software, and increasingly available open source software tools, such as the R statistical platform, are integrated into the LIMS for analysis purposes. Most LIMS provide customization functions to facilitate entry of these results.

Specification Checking

Many standard testing laboratories run analyses to determine if a material is within manufacturing specification limits. The manufacturing process and analysis method usually define these limits. Most LIMS provide a mechanism for these specifications to be stored or retrieved and compared to the results. The specifications are often stored in a database controlled by the clients of the analytical laboratory. Materials that are within specifications can be automatically released. Those that are not can be flagged or operators can be automatically notified regarding the test results.

Coordination and Authorization

In some environments, it is important to validate results before they are released. This usually involves a person other than the analysts checking the results and verifying the procedures. The LIMS can enforce such rules to help ensure that the business processes are followed. In environments where several tests are performed on one material, this role may be to coordinate reporting to the client and to identify and resolve inconsistencies.

Interpretation of Data and Results

The result of research processes is new knowledge. This is generally in the form of written documents with graphics and images that may involve many samples. A LIMS that supports analytical research needs to support the storage of these kinds of results as well as

numerical and tabular results. These documents may be HTML-based documents or more commonly PDF-based reports but the support of a plethora of formats provides the inherent flexibility required for flexible data management and communication.

Report Generation

The output of an analytical laboratory is information that is reported to the client and often affects further actions and decisions. A major function of a LIMS is to improve the efficiency of report generation. To facilitate this process, report templates can be established that are automatically triggered when a step in the workflow is completed. Reports of analysis results, billing, turnaround time, instrument calibration and control charts, justification, and inventory are just a few of the common ones. Because of the variety of clients that analytical laboratories interact with, report generation is an area where there is significant investment in customization to make a LIMS effective.

Archival

The results and reports from an analytical laboratory can be of great economic value. Reference information, historical understanding of processes, solutions to problems, and assigned spectra from structure elucidation efforts represent a few of the valuable resources that need to be maintained, sometimes indefinitely. This information is usually best stored in a knowledge management system specifically designed for this purpose. Organizations may be required to save this information for many years. Archival of this data is generally supported by LIMS.

Summary

The analytical support process exists to aid and enhance the sample generation process. If it cannot be measured, it is hard to improve it. Making the information produced by this process available electronically can significantly enhance its value to an organization. Having measurements available and logically organized is required for any material or process modeling. Quick and easy access avoids duplication of work and speeds up research and problem solving. Computerization of the process requires consideration of interfaces to other information storing or generating systems. These include methods management, manufacturing resource planning and control, electronic laboratory notebooks, instrument interfaces, and reference databases.

LIMS for Spectroscopy

Ever since computers became of a practical size to fit in a spectroscopy laboratory, they have had an ever more

intimate relationship with the spectrometers themselves. Spectrometer vendors have applied them to instrument control, data collection, library searching, and information management. The information management functions of these systems could be considered a LIMS with a focus limited to a particular type of testing. With the exception of chromatography, these systems were limited in scope and did not interface well with laboratory-wide LIMS. Vendors of spectral analysis packages have enhanced their software packages to provide some LIMS functions such as sample and workflow management. While not as flexible overall as the majority of modern LIMS, these niche systems are focused on managing complex data types including chemical structures, and analytical data of various forms.

To aid in sharing spectra obtained using equipment from different vendors, a number of efforts have been made to establish standard exchange formats. In the late 1980s the Joint Committee on Atomic and Molecular Physical Data (JCAMP) published the JCAMP-DX format as a standard for exchange of infrared spectra. This general format was subsequently extended to include mass and NMR spectra. Although JCAMP-DX files are created with small variations from vendor to vendor, this format is supported as an export format by most infrared instrument vendors. The Analytical Instrument Association (AIA) created a netCDF-based Analytical Data Interchange (ANDI) format for chromatography, which received widespread acceptance. After this success, the AIA adopted a standard for mass spectroscopy and began definitions for infrared and NMR. Since that time there have been multiple efforts to develop 'markup languages' compatible with Web-based technologies, which include AnIML (Analytical Information Markup Language) and mzXML and mzData (both for the interchange of mass spectrometry data).

Despite the existence of these standard formats, spectrometer vendors have been slow to include them as export options. This has been a hurdle for spectral analysis and database software vendors who have been required to deliver format converters.

The Dominance of Web-Based Technologies

Since the mid-1990s the world has experienced an explosive growth of the Internet. This growth has primarily been caused by the introduction of graphical Web browsers that provide a simple and intuitive point-and-click environment for access to information. The Web is based on widely accepted and robust standards that are open and simple enough that everyone can participate. It supports most kinds of information (text, graphics, audio, video, binary, etc.) and provides a simple mechanism for adding specialized support. Browsers are now available on all computer platforms and have provided the

paradigm shift to a Web-based world for navigation. LIMS vendors who have not embraced Web-based technologies have, in general, left the market.

Scientists in many analytical research laboratories now use browser-based systems to provide analytical data support for their chemists. Spectroscopic data handling has proliferated in recent years, and commercial solutions have delivered intuitive environments for the viewing and manipulation of sample information, chemical structures, and spectra of various forms, including hyphenated MS spectra and 2D NMR spectra. Data can be searched in a variety of ways including, of course, alphanumeric text but additionally by chemical structure, substructure, and spectral features.

Web-based technologies continue to develop at a breathtaking pace. Text-based searches can easily be conducted in a matter of seconds. Cheminformatics software vendors have fully migrated their technologies to the Web and can perform chemical structure- and substructure-based searches at speeds similar to that for text searches. It is also possible to search vibrational and optical spectra online using many of the standard search algorithms; mass spectra can be searched using basic mass searches, and even 1D and higher-dimensional NMR spectra can be searched by spectral features. The Web is now a standard platform for searching, and while it lags behind in terms of real-time data processing of analytical data, this too will come.

Conclusions

When selecting or developing a LIMS, a laboratory should be clear on why the system is needed and what workflow and business functions it must support. Keeping the installation simple in scope, design, and, most importantly, user interface will help ensure success. As the laboratory's business changes over time, so must its LIMS, and continued investment in information management must be expected. With most companies generally now having competent software developers on staff and more flexible programming environments to develop applications, it is generally more productive for a company to license a series of software components and build unique workflows and a bespoke solution for their laboratory rather than be frustrated at trying to force their processes into an out-of-the-box solution. Nevertheless, in recent years increased vendor competence in the delivery of knowledge management and electronic notebooks systems have produced better systems for research environments. Web-based technologies allow information system interfaces to be developed more quickly, and users familiar with browser technology expect intuitive workflows and graphical user interfaces. With these technology improvements and the necessity

for many laboratory heads to control the flow of information LIMS with better integration and simpler interfaces for spectroscopy have been developed. While they are yet to become ubiquitous in research laboratories, the increasing demands for managing data will drive further development of LIMS in the research environment and certainly in the spectroscopic laboratories.

Introduction

Laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) is considered as one of the most versatile methods for the compositional analysis of solid materials due to its sensitivity and conceptual simplicity. Ever since first feasibility studies were carried out by A. Gray in 1985, the capabilities of LA-ICP-MS in terms of sensitivity, precision, and accuracy have continuously been improved, driven by instrumental advancements and the conception of *smart* tuning and calibration strategies. Consequently, LA-ICP-MS has become a widespread method capable for the element- and isotope-selective analyses of various materials. Furthermore, little or even no sample preparation is needed, making LA-ICP-MS particularly attractive for the analysis of difficult-to-digest materials such as fluorites or silicate glasses, which would otherwise require the application of, say, fluoric acid and subsequent solution nebulization (SN)-based ICP-MS.

The basic layout of an LA-ICP-MS system, as schematically shown in **Figure 1**, consists of a pulsed laser source, beam delivery optics, an airtight sampling cell operated at atmospheric pressure, a transport line, and an ICP-MS detector. Depending on the LA protocol chosen and the material to be analyzed, a heterogeneous mixture of clusters, particles, and aggregates is released during the ablation process, which occasionally results in a 'nonrepresentative' sampling unless matrix-matched

calibration standards are employed. To suppress the occurrence of molecular interferences formed inside the ICP before MS detection and to provide an optimum ion yield required for trace element quantification, only inert gases such as argon and helium are utilized as aerosol carriers. The general performance features of LA-ICP-MS are specified in **Table 1**.

Fundamentals and System Configuration

Modes of Operation

The application of pulsed laser sources as a sampling tool for solid matter can be traced back to the early 1960s when the prospects of LA optical emission spectrometry

Figure 1 Schematic of an LA-ICP-MS system consisting of a laser source, an LA cell, a transport line, and an ICP-MS detector (MS not shown).

Table 1 General performance features of LA-ICP-MS

Factor	Value
Number of elements accessible	> 50
Type of data acquisition	Simultaneous and sequential
Sample uptake rate	0.0001–0.1 $\mu\text{g s}^{-1}$
Spatial resolution	Lateral: < 5 μm , in-depth: > 100 nm
Quantification	Via comparative measurement using external reference materials and internal standardization
Linear dynamic range	0.01–1 000 000 $\mu\text{g g}^{-1}$
Accuracy/precision	1–10% (relative)/1–5% (relative)
Limits of detection	0.01–10 $\mu\text{g g}^{-1}$

(OES) for spectrochemical analyses were explored. From that time on, LA-based analytical methods, although inherently destructive, have been applied to both bulk and spatially resolved analyses of, say, minerals, metals, and biological tissues. Various instrumental schemes have been conceived to adapt the performance characteristics to ever-growing standards. Among these, optical as well as mass spectrometric detection methods using primary emission of photons and ions or external plasma sources have been implemented. The following section covers fundamental aspects concerning the LA process, aerosol transportation, as well as the ion formation, extraction, and detection by ICP-MS. In addition, practical issues such as the adequate choice of a sampling cell and ICP-MS tuning strategies are comprehensively discussed.

Aerosol Formation and Transportation

To achieve an optimum performance of analysis, sample material released by LA (1) should exactly match the bulk composition, (2) be converted into an aerosol that can efficiently be transported to the detector site, and (3) must completely be decomposed inside the ICP source. For this purpose, Nd:YAG laser sources emitting nanosecond (ns) pulses (5–10 ns) in the mid- and far-ultraviolet (UV) spectral range down to 213 nm (fifth harmonic of the fundamental radiation at 1064 nm) have been employed for LA. However, the formation of micrometer particles during the initial stage of LA has been found to strongly affect precision and accuracy of Nd:YAG-based LA-ICP-MS analyses since they are known to insufficiently evaporate when penetrating through the ICP, resulting in spiky and intensively drifting signals. In fact, nonaccurate quantification of UV-transparent materials as a result of incomplete evaporation has been identified as a central issue preventing UV-ns-LA-ICP-MS at 266 nm (fourth harmonic) and 213 nm to be accepted as *the* universal tool for the comprehensive analysis of both opaque and highly transparent materials. In contrast, the utilization of laser systems emitting in the vacuum UV (VUV) spectral range at 193 nm significantly suppresses the formation of micrometer particles, enabling one to perform more reliable analyses for a wider range of material. In recent years, VUV-ns-LA by either ArF-type excimer or optical parametric oscillator (OPO)-type solid-state laser systems has been proven to create well-conditioned aerosols in terms of mean particle size and composition.

However, the application of ns laser radiation has been found to provoke the formation of a so-called heat-affect zone whenever metals and semiconductors are analyzed. In such cases, material redistribution due to thermal diffusion occurs even if the local temperature buildup during the laser-matter interaction is intense enough

to evaporate the most refractory elements. As a result, preferential evaporation, that is, a cumulative enrichment or depletion of certain constituents, may arise in the course of analysis. Moreover, the pulse energy is partly absorbed by the plasma built up above the exposed area, which, in turn, may alter the composition of aerosol particles formed during expansion. Both *zone heating* and *plasma shielding* are obviously related to pulse duration, which governs the dynamics of the LA process. To suppress these effects, the LA-induced phase transition (solid–liquid–gaseous or ‘metastable’ liquid) must be accomplished before energy starts to diffuse out of the irradiated volume or to interact with ejected material, respectively. In other words, the pulse duration must fall below the material-specific, thermal relaxation time defined by the strength of the electron–phonon coupling, which, according to the literature, is well below 1 picosecond (ps) for conducting matter. Therefore, decreasing the pulse duration down to the femtosecond (fs) range has been suggested to improve the ablation characteristics and to realize the ideal concept of *stoichiometric* sampling. Over the past years, the composition of primary aerosols has been extensively studied. Metallic and dielectric aerosol particles produced by fs-LA of brass and silicate glass were classified by low-pressure impaction or filtering and analyzed using total reflection X-ray fluorescence (TXRF) or SN-ICP-MS, respectively. It was shown that the application of fs pulses permits one to create aerosols predominately consisting of mesoscopic particles in an approximate size range between 10 and 100 nm, which (1) tend to form fractal aggregates and (2) whose composition strongly depends on the individual particle size. (From an analytical point of view, the formation of aggregates as described earlier in this section proves favorable since it reduces potential diffusion losses during the transport period. Furthermore, these aggregates expose a larger contact surface to the ICP compared to a single particle of the same mass and, thus, increase the probability for complete vaporization inside the ICP.) However, the overall composition of aerosols formed still matches the bulk material, as can be seen in **Figure 2**.

Several mechanisms potentially involved in the formation of aerosols during LA using different pulse durations have been discussed. These include, for instance, nucleation and particle condensation from supersaturated vapor, phase explosion, or hydrodynamic instabilities. Nevertheless, condensational growth is considered to be the dominant mechanism even though it results in the formation of particles <100 nm, due to the rapid cooling rate of the expanding material that is of the order of 10^{11} K s^{-1} . However, scanning electron microscopy (SEM) of deposits indicates the presence of particles >100 nm, in particular, if LA is performed in an argon atmosphere using energy densities well above the range of $5\text{--}10 \text{ J cm}^{-2}$. Coexisting processes that can result

Figure 2 Particle size distribution and composition of an aerosol produced by fs-LA of brass using argon as in-cell carrier gas.

in the formation of such particles are, for example, coalescence or aggregation of solidified particles. In contrast, phase explosion, that is, the explosive-like relaxation of a supercritical liquid, could, in principle, act as a single source for both smaller and larger particles since it produces a mixture of droplets and vapor.

Owing to the nonuniform, that is, size-dependent, composition of aerosols produced, the chance of material losses during the transport period as a result of diffusion or electrostatic, thermophoretic, inertial, and gravitational settling has extensively been discussed as possible sources for compositional changes that may affect the accuracy of analysis. Early assumptions about the transport efficiency of laser-produced aerosols yielded somewhat inconsistent values ranging from 10% up to 60%, which were measured by optical particle counting (OPC) and chemical analyses of filtered particles taking into account the mass released during LA. However, recent studies suggest the transport efficiency to be in between 90% and 100%, which furthermore appears to be less dependent on cell geometry, volume, and flow conditions chosen, implying that virtually any transport system is appropriate for analysis. Transport efficiencies were determined by aerosol impaction and pre- and post-LA target weighing, which represents an extremely powerful approach since it provides complementary data on particle size distributions and the overall as well as size-dependent aerosol compositions. It thus comprises all information relevant to the analysis of aerosols generated by LA. However, values calculated this way do not take into account material deposited around the crater rim, which is negligible for LA under helium atmosphere but cannot be disregarded if heavier gases such as argon

are used. In fact, the relative fraction of debris accumulating in an argon atmosphere was found to be larger than 30% for crater diameters of approximately 50 μm.

As already stated earlier in this section, LA cells and transport systems commonly used show only minor differences in terms of their overall throughput and, hence, the integral sensitivity achievable. Therefore, criteria for an adequate choice of LA cells and transport systems rather aim for practical performance features such as quick and easy sample handling/exchange or the degree of aerosol dispersion over the cross section of the transport tube attached to the cell, which defines precision and, to some extent, also the accuracy of analysis. A high degree of aerosol dispersion can be provided by either turbulent in-cell carrier gas flows or a 'dispersive' element (e.g., nozzle) inserted downstream of the transport line. For a certain category of applications such as large-scale mapping, rapid depth profiling, or comprehensive 3-D analyses, a homogenization of aerosol particles originating from successive LA events is less desirable since an efficient dispersion inside the LA cell increases their residence time and, thus, the speed of analysis. In those cases, the maximum laser repetition rate applicable is given by the reciprocal value of the in-cell residence time, provided that the signal dispersion during the transport period can be neglected.

The design adaptation of LA cells/transport systems is usually performed by trial and error, which turns out to be time consuming and, thus, less satisfactory concerning a quick changeover to different, application-dependent requirements. To perform a more time- and cost-effective adaptation, over the past years, modeling by computational fluid dynamics (CFD) has been suggested as an alternative

way even allowing for an automated design optimization if evolutionary algorithms are implemented.

Analysis by ICP-MS

Depending on the mass resolution, sensitivity, and precision required, ICP-MS analyses of laser-produced aerosols are carried out by quadrupole (Q), sector field (SF), or time-of-flight (TOF)-type instruments that were originally designed for SN-based applications. Most commonly, ICP-MS devices equipped with fast-scanning Q-filters are chosen due to a linear dynamic range that covers up to nine orders of magnitude, thus permitting the acquisition of main constituents and minor and trace elements and rapid acquisition cycles over the entire mass range. Furthermore, state-of-the-art Q-filters offer a mass resolution sufficient for the analysis of nearly all elements accessible by ICP-MS, except for those that are blocked by isobaric or molecular interferences such as $^{16}\text{O}^{16}\text{O}^+$ on $^{32}\text{S}^+$, which cannot be overcome by switching to another isotope. In these cases, Q-based instruments equipped with dynamic reaction cells or high-resolution SF-MS ($m\Delta m^{-1} \approx 10,000$), or even a combination of both, need to be utilized. A list of elements accessible by ICP-MS is given in **Figure 3**.

Although the gas and ionization temperatures attainable by an ICP operated under standard conditions may exceed values of 7000 K, the upper size limit of primary particles that can be completely evaporated and hence ionized was

found to be restricted to values of approximately $0.15\ \mu\text{m}$. Assuming the aerosols to consist of particles with size-dependent compositions, the formation enthalpy of which, differs from that of those produced by LA of the calibration standard, the axial position for complete evaporation/ionization inside the ICP is supposed to strongly depend on both element and material under study. As a consequence, the ion distribution pattern in front of the ICP-MS interface strongly varies, resulting in a non-representative extraction unless matrix-matched calibration is performed. Furthermore, the degree of aerosol dispersion that defines the coagulation probability of smaller aggregates when reaching the ICP may result in the formation of larger particles. Those particles would, obviously, expose a smaller contact surface to the ICP, resulting in a larger penetration depth toward the interface.

In fact, there has been no model yet designed that is adequate to predict the formation of such patterns due to its complexity involving the penetration depth of particles and mass-dependent diffusion of ions off axis. Therefore, system tuning is still performed on the basis of general performance indicators such as sensitivity, precision (internal RSD), or the oxide formation rate taking into account, for example, the ThO^+/Th^+ intensity ratio, which enables one to suppress the occurrence of molecular interferences. For these purposes, the power supplied to the ICP as well as gas flow rates and the axial torch position are adjusted. However, changing the ICP settings and, in particular, the helium flow rate is

known to alter both the interface pressure and the temperature and, thus, the optimum distance between sampler and skimmer cone. Consequently, the overall throughput of ions decreases, making an adaptation of the pumping capacity and extraction voltage necessary. For extraction-type ion optics, the potential is typically set to several hundred volts negative. Therefore, the charge separation of electrons and ions already happens during the acceleration period, which occasionally degrades the mass resolution due to space charge defocusing. In contrast, ICP-MS instruments equipped with ion optics set to positive voltages keep up the 'quasi-neutral' plasma state for a longer duration and are less susceptible to space charging. (Space charge effects affect not only the mass resolution achievable during m/z separation but also the ion transmission through the interface and further downstream, in particular, for low-mass elements that are more strongly deflected by the electrostatic forces built up in the ion beam. As a result, the ion transmission typically covers a range of approximately three orders of magnitude from ^7Li up to ^{238}U .)

One of the most obvious advantages about the analysis of 'dry,' that is, laser-produced, aerosols is the absence of any solvent-induced spectral interference that, of course, restricts the selectivity of SN-ICP-MS. However, analyses carried out by LA-ICP-MS are often subject to other sources of interferences that affect its quantification capabilities or the quality of results achieved. Depending on the composition of the material under study, isobaric isotopes, polyatomic ions, and doubly charged ions can be formed. Furthermore, molecular ions such as $^{40}\text{Ar}^{16}\text{O}^+$ and $^{16}\text{O}^{16}\text{O}^+$ may occur at variable levels resulting in count rates of up to several millions per second. Therefore, the utilization of high-purity (99.999%) plasma and aerosol carrier gases is required to prevent the occurrence of primary interferences arising from gas impurities and secondary, Ar-based adducts.

Increasing the mass resolution to values of a few thousands using, for example, SF-ICP-MS allows one to suppress many of those interferences, in particular, with respect to the analysis of transition elements. However, SF instruments commonly used are still not capable of resolving of isobaric ions and certain polyatomic ions, especially some of the argides (ArX^+) formed in the intermediate m/z range. In addition, an increased mass resolution lowers the ion transmission and, thus, sensitivity. In contrast, the operation of reaction or collision cells pressurized with hydrogen, helium, or NH_3 allows for the suppression of, say, several Ar-based interferences while keeping the ion transmission almost constant.

ICP-MS Detection Schemes

As indicated in the section 'Analysis by ICP-MS' almost any type of MS detection scheme has been combined

with ICP ion sources. In this context, Q-filters and fast-scanning SF devices are most commonly installed due to their feasibility of measuring nearly all elements that are accessible by ICP-MS. Moreover, they provide settling times ranging from 0.1 (Q) to 1 ms (SF) for electrostatic scans and permit the acquisitions of full replicates, that is, m/z scans, over the chosen range in 1 s or less. Nevertheless, both Q and SF instruments inherently perform sequential measurements implying that data points acquired within one replicate do not exactly correlate, which would be desirable if, for instance, homogeneity studies with high spatial and temporal resolutions are accomplished. In such cases, laser-produced aerosols should be analyzed by either TOF-SF-MS or multi-collector (MC)-SF-MS. Whereas the former type of spectrometer separates monoenergetic ions according to their drift time in a linear tube or reflectron-type arrangement – therefore representing an extremely fast but still sequential detection – the latter one operates several Faraday cups for real simultaneous acquisition, which, however, limits the m/z coverage. Depending on the dimensioning of the SFs used, the range detectable by MC-ICP-MS is restricted to approximately ± 10 –20% around the central m/z value set.

Data Processing, Calibration, and Quantification

The quantification capabilities of LA-ICP-MS critically depend on the availability of suited reference standards for calibration, which, in the best-cases, exactly match the sample composition. In this way, a wide variety of geological, mostly SiO_2 -based, materials have already been successfully analyzed. Nevertheless, accurate quantification usually requires the definition of an internal standard to compensate for matrix-dependent LA rates, that is, the amount of material released per shot. Thus, the concentration of, at least, one matrix constituent of sample and reference material must be known from complementary analytic techniques such as X-ray fluorescence or electron probe micro analysis (EPMA). If so, elemental concentrations can be calculated as follows:

$$C_{\text{A,sam.}} = I_{\text{A,sam.}} \cdot \frac{C_{\text{IS,sam.}}}{I_{\text{IS,sam.}}} \cdot \frac{C_{\text{A,cal.}}}{I_{\text{A,cal.}}} \cdot \frac{I_{\text{IS,cal.}}}{C_{\text{IS,cal.}}} \quad [1]$$

where C is the concentration value and I the signal intensity. Subscripts: 'A = analyte,' 'IS = internal standard,' 'sam. = sample,' and 'cal. = calibration standard.'

Several strategies of circumventing the utilization of an internal standard such as (1) normalizing on sum intensities, (2) determining the ablated mass by OPC or pre- and post-LA sample weighing (mass normalization), or (3) admixing of isotope dopants with known

composition have been conceived. Among these, sum intensity normalization is probably regarded as the most practicable approach to extend the quantification capabilities of LA-ICP-MS. It, however, requires information about the content of all major and minor elements to be analyzed, which, in addition, must be accessible by ICP-MS. Assuming Y to be the sum of these, the concentration of a specific element concentration is given as follows:

$$C_{A,\text{sam.}} = \frac{Y \cdot C_{A,\text{cal.}} \cdot I_{A,\text{sam.}}}{I_{A,\text{cal.}} \cdot \sum_{i=1}^n \frac{I_{A,\text{sam.}}^i \cdot C_{A,\text{sam.}}^i}{I_{A,\text{cal.}}^i}} \quad [2]$$

Apparently, quantification by internal standardization using matrix-matched calibration standards yields the most accurate data and should, therefore, always be preferred. However, the persistent lack of reference standards often makes necessary the application of non-matrix-matched calibration or even solution-based calibration strategies by simultaneous aspiration of liquid standards.

Elemental Fractionation

Since the early 1990s, a series of authors have reported on nonrepresentative and temporally drifting elemental ratios commonly defined over two sequent parts of the acquired ICP-MS signal. Both phenomena – also named elemental fractionation – represent *the* limiting factors all analyses based on non-matrix-matched calibration are subject to. The examination of these effects has been reported a principal matter due to their complexity involving laser-, transport-, and ICP-induced elemental fractionation. The following example shall illustrate the common practice of data treatment and the difficulties any interpretation of LA-ICP-MS data in terms of fractionation underlies.

Owing to the above-mentioned lack of reference materials, analyses performed by LA-ICP-MS often demand the utilization of non-matrix-matched calibration and internal standardization to correct for varying, matrix-dependent ablation rates. The mean of elemental ratios derived from this procedure may exceed, reflect, or fall below the values that correspond to the actual bulk composition depending on the LA protocol and the acquisition period taken for analysis. Timing and width of this period are parameter dependent and, therefore, based on empirical knowledge since the relative contribution of each fractionation source – denoted as F_{laser} , $F_{\text{transport}}$, and F_{ICP} – during the ablation process cannot be predicted on a quantitative basis. As already suggested earlier in this section, F_{laser} , $F_{\text{transport}}$, and F_{ICP} are correlated, implying that the overall fractionation is – as a

first approximation – of multiplicative nature, that is,

$$\left. \frac{R_{\text{el.,a}}}{R_{\text{el.,b}}} \right|_{\text{exp.}} = \underbrace{F_{\text{laser}} \cdot F_{\text{transport}} \cdot F_{\text{ICP}}}_{F_{\text{tot.}}} \times \left. \frac{R_{\text{el.,a}}}{R_{\text{el.,b}}} \right|_{\text{theor.}} \quad [3]$$

Here, $R_{\text{el.}}(\text{exp.})$ and $R_{\text{el.}}(\text{theor.})$ denote the measured and expected elemental responses, respectively. Subscripts a and b refer to the elements analyzed. Apparently, numerous combinations of eqn [3] exist that result in the correct elemental ratio, and there is no possibility to judge if the system is really fractionation free within the acquisition period, that is, F_{laser} , $F_{\text{transport}}$, and F_{ICP} equal to 1, or if the individual sources simply compensate each other in a way that only the overall fractionation index $F_{\text{tot.}}$ equals to 1. From an analytical point of view, any combination resulting in $F_{\text{tot.}} = 1$ would be acceptable provided that $F_{\text{tot.}}$ of the standard material also equals to 1. Unfortunately, experimental conditions that allow for fractionation-free analyses in the former sense are dependent on the matrix and all parameters that affect the LA process as well as the operational conditions of the ICP.

This line of arguments also applies to the marginal cases of small acquisition periods or stationary elemental ratios. It, however, needs to be stressed that stationary elemental ratios, that is, the absence of temporal drifts, do *not* necessarily imply accurate analyses. For instance, raster-mode LA of homogeneous materials provide constant elemental ratios that often depart from the actual bulk composition due to incomplete evaporation of micrometer particles inside the ICP. However, the presence of temporal changes during the analysis of non-matrix-matched materials can yield correct elemental concentrations even if $F_{\text{tot.}}$ of sample and standard material are not equal to 1 but identical. This rare situation occurs when the fractionation properties between the calibration standard and the sample to be analyzed are coincidentally equal or are adjusted to be the same via proper tuning of LA and ICP conditions.

Despite the difficulties of identifying the sources of elemental fractionation, empirical studies indicate that fs-LA generally allows for the production of ‘stoichiometric’ aerosols that are efficiently transported and, thus, to greatly suppress F_{laser} and $F_{\text{transport}}$. As a consequence, inaccuracies mainly originate from ICP-related effects, that is, nonrepresentative ion extraction due to the formation of aerosols with incongruent structural (composition, particle size distribution, degree of aggregation, and dispersion) and thermal properties (overall and particle size-dependent enthalpy of formation) resulting in different ion distribution patterns.

Figures of Merit/Selected Applications

According to the literature, geological applications have always been the driving force for developments and

improvements in LA-ICP-MS. Trace element analyses of different mineral phases, fluid/melt inclusions, and gemstones with a lateral resolution of $<5\ \mu\text{m}$ have been reported. Apparently, operating LA-ICP-MS systems in this range somewhat restricts their detection capabilities since the resolution set for analysis predefines the amount of material supplied to the ICP-MS and, thus, the sensitivity. Increasing the crater size to values above $40\ \mu\text{m}$ permits one to measure concentrations as low as few micrograms per gram for elements with $m/z > 80$. Depending on the ICP-MS instrument used, 10^3 – 10^4 cps per $\mu\text{g g}^{-1}$ can be obtained. However, N, O, and H cannot be quantified due to the atmospheric nature of ICP used for MS detection. Furthermore, the ionization potential provided by ICPs supplied with Ar does not allow access to ^{19}F detection.

LA-ICP-MS using non-matrix-matched calibration has been applied to a wide range of analytical tasks. For instance, rare earth element concentrations of geological materials could be accurately quantified using SiO_2 -based reference materials (NIST series) in combination with Ca as the internal standard. In addition, the production of novel glass standards such as MPDING or the USGS series helped to further improve the accuracy of mineral analyses. It was shown that trace element concentrations can be measured with an accuracy and precision of a few percent. The uncertainty, however, depends on the homogeneity of reference materials at the micrometer scale, which often is *not* given. One remaining challenge is the age determination of zircons by LA-ICP-MS being used as a chronometer for geological events. In fact, local phase changes during the LA process were found to result in accuracies insufficient for dating purposes unless matrix-matched calibration materials (GJ-1 or 91500, SL13) were employed. Furthermore, 1- or 2-D imaging by LA-ICP-MS has become a useful tool to visualize element concentrations at a high spatial resolution. Recently, compositions of stalagmites and corals were determined by LA-ICP-MS in order to reconstruct the elemental pattern implanted over time, giving insight into prehistoric climate changes. Other applications are, for example, forensic provenance studies or archaeometric fingerprints, which both require the analysis of small amounts of sample material and less destruction.

Conclusion

High sensitivity and spatial resolution make LA-ICP-MS an excellent tool for trace element microanalysis (lateral: $\approx 5\ \mu\text{m}$; in-depth: $\approx 100\ \text{nm}$) of solid materials, offering detection limits at a microgram-per-gram level and below. Ever since its conception in the mid-1980s, LA-ICP-MS has been applied to the analysis of

scientific, industrial, and technologically relevant materials. In the course of time, LA-ICP-MS has therefore gained access to numerous disciplines such as biology, metallurgy, archaeology, material science, environment science, gemology, or medicine, whereas its main field of application is still the element- and isotope-selective analyses of geological sample material. According to the literature, more than 800 papers have been published and the interest in LA-ICP-MS is continuously growing due to improved instrumentation and refined quantification strategies. At the moment, VUV-ns-LA-ICP-MS is certainly considered state of the art. Nevertheless, the utilization of ultrashort, that is, fs, laser pulses represents a promising instrumental advancement allowing for the production of dielectric *and* (semi-)conducting aerosols, whose composition exactly matches the one of the bulk, and, thus, for performing accurate analyses for a wider range of materials. The future perspectives of LA-ICP-MS for, for example, the trace element analysis of sub-micrometer or even nano-sized features, will, however, strongly depend on the progress the ICP-MS instrumentation needs to make in terms of sensitivity and the suppression of ICP-induced fractionation. First feasibility studies already demonstrate nano-scale LA-ICP-MS analyses applying near-field techniques to be appropriate for the quantification of main constituents.

$\sigma_{ik}(\nu)$	cross section for transition $ k\rangle \leftarrow i\rangle$
τ	upper-state lifetime
ω	laser (pump) frequency
Ω	modulation frequency
Ω_0	local oscillator frequency

Introduction

The applications of lasers to atomic and molecular spectroscopy has revolutionized this field. Although methods in classical spectroscopy of electronic transitions using large grating spectrographs or interferometers have brought a wealth of information on molecular structure and dynamics, the new techniques of laser spectroscopy have by far surpassed the capabilities of former methods with regard to sensitivity and spectral or time resolution.

This article reviews these new spectroscopic techniques, their applications and some of the results obtained so far; it will be restricted to the spectroscopy of free atoms and molecules and does not include solid-state spectroscopy.

Various techniques of sensitive absorption spectroscopy, including nonlinear techniques, which allow a spectral resolution below the Doppler width are described first. These techniques are termed sub-Doppler-spectroscopy and include linear spectroscopy in collimated molecular beams, nonlinear saturation and polarization spectroscopy, and Doppler-free two-photon spectroscopy. Emission spectroscopy, which covers laser-induced fluorescence as well as stimulated emission methods, is described next. The assignment of complex molecular spectra is greatly facilitated by optical-double resonance methods, which are treated together with optical pumping. The development of ultrashort laser pulses in the picosecond to femtosecond time domain has opened a wide area for investigations of molecular dynamics, intramolecular and intermolecular energy transfer, fast collision-induced relaxations, and detailed real-time studies of chemical reactions by observation of the forming and breaking of chemical bonds. This fascinating and rapidly expanding field of femtosecond chemistry is covered briefly. The final section discusses some aspects of coherent spectroscopy with pulsed and CW lasers that rely on the coherence properties of the laser light and on the coherent preparation of atomic or molecular states. Techniques such as quantum beat spectroscopy, correlation spectroscopy and STIRAP are described and their relevance for the electronic spectroscopy of atoms and molecules is outlined.

Sensitive Absorption Spectroscopy

In classical absorption spectroscopy, the intensity I_T of a light beam transmitted over a pathlength L through a sample of absorbing molecules with absorption coefficient α (cm^{-1}) is compared with the incident intensity I_0 . According to Beer's law of linear absorption,

$$I_T = I_0 \exp(-\alpha L) \approx I_0(1 - \alpha L) \quad \text{for } \alpha L \ll 1 \quad [1]$$

the absorption can be written as

$$\alpha L \approx \frac{I_0 - I_T}{T_0} \quad [2]$$

The smallest still detectable absorption is limited by intensity fluctuations of the incident intensity I_0 and by detector noise. The absorption coefficient $\alpha = N_i \sigma_{ik}$ is the product of number density N_i of molecules in the absorbing level $|i\rangle$ and absorption cross section $\sigma_{ik}(\nu)$ for the transition $|k\rangle \leftarrow |i\rangle$. The minimum detectable number N_i of absorbing molecules

$$N_i = \frac{\Delta I_{\min}}{I_0 L \sigma} \quad [3]$$

is then given by the minimum difference $\Delta I_{\min} = I_0 - I_T$ that still can be safely measured. For a given value of $\Delta I_{\min}$, the detection sensitivity can be increased by making the product $I_0 L \sigma$ as large as possible. The various sensitive techniques of laser absorption spectroscopy attempt to minimize $\Delta I_{\min}$ as well as to maximize $I_0 L \sigma$.

High-Frequency Modulation Spectroscopy

For high-resolution laser absorption spectroscopy, a narrow-band tuneable CW laser can be used. Possible candidates are dye lasers, Ti:sapphire or other vibronic solid-state lasers, and the variety of tuneable semiconductor diode lasers, which cover a spectral range from the blue to the mid-infrared. Of particular importance are the optical parametric oscillators that have been brought to reliable operation in the pulsed as well as in the CW mode with single-mode performance. They can now span the spectral region from 500 to 5000 nm.

When the output of such a tuneable monochromatic laser is sent through an electrooptic modulator, the phase and thus the frequency of the transmitted laser wave is modulated and the frequency spectrum consists of the carrier and two sideband frequencies, where the sidebands have opposite phases (Figure 1). At a modulation frequency of $\Omega = 1$ GHz, the separation of the sidebands from the carrier is about equal to the Doppler width of the absorption lines. If this modulated laser beam is detected after transmission through the absorption cell, the output of a lock-in, tuned to the frequency Ω , will not show any signal as long as neither the carrier nor the sidebands overlap with an absorption line, since the beat signals between carrier and the two sidebands exactly cancel. Note also that any fluctuations of the laser intensity are automatically subtracted. If, however, one of the three frequencies coincides with a molecular absorption line, the exact balance is perturbed and a detector signal is generated. When the laser frequency ω is tuned over an absorption line, the measured signal profile $S(\omega)$ is similar to the second derivative of the absorption profile $\alpha(\omega)$.

Since lock-in detectors now available cannot measure frequencies above 100 MHz, the output of the detector is heterodyned with a stable local oscillator of frequency Ω_0 and the beat signal with frequency $(\Omega - \Omega_0)$ is sent to the lock-in.

The sensitivity of this modulation spectroscopy is two to three orders of magnitude higher than in conventional

Figure 1 Principle of modulation spectroscopy. (a) apparatus; (b) sidebands of phase modulation; (c) line profile of the signal $S(\omega)$.

spectroscopy and reaches a minimum detectable absorption of $\alpha L < 10^{-7}$. Using multiple-path absorption cells (Herriot cells) and balanced detectors for detection of reference and transmitted beams, absorption coefficients as low as $\alpha \leq 10^{-10} \text{ cm}^{-1}$ can still be measured.

Excitation Spectroscopy

Instead of measuring the transmitted laser intensity, the photons absorbed by the sample molecules can be directly detected because they excite the absorbing molecules into a state $|k\rangle$ that emits fluorescence (Figure 2). The rate of detected fluorescence photons is

$$\dot{n}_{\text{FI}} = \dot{n}_{\text{abs}} \cdot \eta_{\text{m}} \cdot \varepsilon \cdot \eta_{\text{k}} \quad [4]$$

where $\dot{n}_{\text{abs}}$ is the rate of absorbed laser photons, $\eta_{\text{m}} \leq 1$ is the quantum efficiency of the excited atom or molecule, ε is the collection probability of the emitted fluorescence and η_{k} is the quantum efficiency of the detector. With 1 W incident laser power at $\lambda = 500 \text{ nm}$, a collection efficiency of $\varepsilon = 0.1$, quantum efficiencies $\eta_{\text{m}} = 1$ and $\eta_{\text{k}} = 0.2$ and an absorption probability of $\alpha L = 10^{-15}$, we obtain a photon counting rate of $60 \text{ photons s}^{-1}$, which gives a signal-to-noise ratio of 6 at a time constant of 1 s and a dark current of $10 \text{ photons s}^{-1}$.

For selected atomic transitions, the upper level may decay only into the initial lower level (true two-level system). In this case the same atom can be excited many times during its flight time T through the laser beam. If its upper-state lifetime is τ , the number of fluorescence photons emitted per second may be as high as T/τ (photon burst), if the laser is intense enough to saturate the transition.

Figure 2 Level scheme of excitation spectroscopy.

Ionization Spectroscopy

The absorption of a photon in the transition $|i\rangle \rightarrow |k\rangle$ can be also detected by ionizing the molecule in the excited state $|k\rangle$ by a second photon (Figure 3). If the intensity of the second laser is sufficiently high, the ionizing transition may be saturated, which implies that every excited molecule is ionized. Since the ions are extracted from the ionization volume by an electric field that focuses them onto the cathode of an ion multiplier, the detection efficiency can reach 100%.

This makes the technique very sensitive and in favourable cases single absorbed photons can be monitored. Since the first transition $|i\rangle \rightarrow |k\rangle$ can be readily saturated, this also implies that single molecules can be detected.

In case of pulsed lasers, the laser power is sufficiently high to allow saturation of the two transitions even without focusing or with only weak focusing. If the ionization energy is high, two or more photons might be

Figure 3 Level scheme of ionization spectroscopy.

required for the ionizing step (REMPI, resonant multi-photon ionization). With CW lasers, tight focusing is required to reach the necessary high intensity.

The further advantage of ionization spectroscopy is the mass-selective detection of the ions by means of a mass spectrometer. This allows the detection of specific isotopes in the presence of other species. With pulsed laser ionization, a time-of-flight mass spectrometer offers the best choice; for CW lasers, a quadrupole mass spectrometer is suitable.

Absorption Spectroscopy in Molecular Beams

The spectral resolution for absorption spectroscopy in the gas phase is generally restricted by the Doppler width of the absorption lines. If the laser beam crosses perpendicularly a molecular beam that is formed by molecules passing from a reservoir through a narrow nozzle A into vacuum and is collimated by a slit of width b at a distance d from the nozzle (**Figure 4**), the velocity components of the beam molecules parallel to the direction of the laser beam are reduced, owing to the geometric collimation. This reduces the Doppler width by a factor $\varepsilon = b/d$, which equals the collimation ratio $b/d \approx 0.01$ of the molecular beam.

Besides the increase in spectral resolution, supersonic molecular beams have the additional advantage that during the adiabatic expansion the molecules transfer a large fraction of their internal energy E_{int} into directed flow energy. This means that the molecules are cooled and their population distribution $N(E_{\text{int}})$ is compressed into the lowest rotational–vibrational levels. This reduces the number of absorbing levels and therefore simplifies the absorption spectra considerably and facilitates the assignment of complex spectra of larger molecules.

Nonlinear Sub-Doppler Spectroscopy

The Doppler limit in spectral resolution can be also overcome by nonlinear spectroscopy, which is based on saturation of absorbing transitions resulting in a partial or

complete depletion of the population in the absorbing level.

The scheme of saturation spectroscopy is depicted in **Figure 5**. The output beam of a single-mode tuneable laser is split into a strong pump beam and a weak probe beam, which pass in opposite $\pm z$ directions through the sample cell with length L . Only those molecules with velocity components v_z can absorb the pump photons on the transition $|i\rangle \rightarrow |k\rangle$ with centre frequency ω_0 , which are Doppler shifted into resonance with the laser frequency ω . This gives the relation

$$|\omega_0 - \omega \pm kv_z| \leq \gamma$$

where γ is the homogeneous line width of the transition. Since the wave vector k of the probe is opposite to that of the pump beam, the Doppler shifts for pump or probe absorption are opposite. A molecule can only interact with both beams if its Doppler shift is smaller than the homogeneous width γ , i.e. $|k \cdot v_z| < \gamma/2$. In this case the probe absorption is decreased due to the saturation by the pump, which depletes the number N_i of absorbing molecules. When the laser frequency ω is tuned over the Doppler broadened absorption profile, the absorption $\Delta I = \alpha L$ of the probe intensity shows a dip at the line centre (Lamb dip) with a spectral width γ that may be two orders of magnitude smaller than the Doppler width (**Figure 5b**). This results in a corresponding peak in the transmitted probe intensity $I_T \approx I_0(1 - \alpha L)$ (**Figure 5c**).

The disadvantage of this simple arrangement is its low sensitivity, since a tiny change of the transmitted intensity has to be detected. If the pump intensity is chopped and the probe transmission is recorded with a lock-in detector, tuned to the chopping frequency, the difference of the transmitted intensities with and without saturation is monitored. This eliminates the Doppler-broadened background and yields Doppler-free profiles (i.e. the Lamb peaks) with higher sensitivity (**Figure 5d**).

Still higher sensitivities can be reached with polarization spectroscopy, in which the sample is placed

Figure 4 Sub-Doppler spectroscopy in a collimated molecular beam.

Figure 5 Saturation spectroscopy: (a) experimental scheme; (b) Lamb dip at the centre of the Doppler-broadened absorption profile; (c) Lamb peak; (d) difference of the transmitted probe intensity with and without pump.

between two crossed polarizers (**Figure 6**). The circularly polarized pump beam with intensity I_2 induces transitions with $\Delta M = 1$ (M = quantum number of the projection of the total angular momentum J on the laser beam axis), causing a partial orientation of the otherwise randomly orientated molecules, owing to non-uniform saturation of the different M -sub-levels. This makes the otherwise isotropic gaseous medium birefringent and causes a rotation of the polarization vector of a linearly polarized probe wave with intensity $I_1 \ll I_2$, passing in the opposite direction through the sample. However, this happens only if the probe wave interacts with the same molecules as the pump wave, i.e. if these molecules have velocity components $|v_z| \leq \gamma/2k$, just as in the case of saturation spectroscopy.

Since without saturation no signal is detected through the crossed polarizers, the method suppresses the background and therefore reduces much of the noise, resulting in a higher signal-to-noise ratio.

Doppler-Free Two-Photon Spectroscopy

When two photons interact simultaneously with a molecule, a two-photon transition $|i\rangle \xrightarrow{h\nu_1+h\nu_2} |k\rangle$ can occur if

the two levels $|i\rangle$ and $|k\rangle$ have the same parity and differ in their angular momenta J by $\Delta J = 0, \pm 2$. This allows the excitation of high-lying electronic states in atoms or molecules, such as Rydberg states. Since the transition probability for two-photon transitions is much smaller than for one-photon transitions, generally pulsed lasers with high peak powers are used. However, two-photon transitions have been observed even with CW lasers. If the two photons come from two opposite beams of the same tuneable lasers, the two-photon transition in a molecule moving with velocity component v_z requires the energy conservation

$$\begin{aligned} E_k - E_i &= (h\omega_1 - kv_z) + (h\omega_2 + kv_z) \\ &= 2\hbar\omega \quad \text{for } \omega_1 = \omega_2 = \omega \end{aligned} \quad [5]$$

independent of the molecular velocity v_z . This means that all molecules in level $|i\rangle$, independent of their velocities, contribute to the two-photon signal at a laser frequency $\omega = (E_k - E_i)/2\hbar$. This is different from saturation or polarization spectroscopy where only a small subgroup of molecules with $|v_z| \leq \gamma/2$ can absorb both laser beams. Despite the smaller transition probability, it

Figure 6 Polarization spectroscopy. (a) example $\Delta M = +1$ transitions; (b) experimental scheme; (c) circular polarizations of pump and probe waves.

therefore yields comparable signal magnitudes as for the other nonlinear techniques. This is illustrated by **Figure 7**, which shows the Doppler-free two-photon transition $5S_{1/2} \leftarrow 3S_{1/2}$ of sodium-atoms, measured by Cagnac and co-workers.

Emission Spectroscopy

Classical emission spectroscopy is based on excitation of atoms or molecules into higher electronic states by electron impact (in gas discharges), photon absorption or thermal excitation at high temperatures (in star atmospheres). Excitation by narrow-band lasers may result in the selective population of wanted levels, which emit their excitation energy as fluorescence photons. Such a laser-induced fluorescence (LIF) spectrum is much simpler than the emission spectrum of a gas discharge, where the superposition of fluorescence from many emitting levels is observed.

Measurements of spectrally resolved LIF allows the determination of the final levels into which the

fluorescence is emitted (**Figure 8a**). This gives access, for example, to high vibrational-rotational levels in the electronic ground state that are not thermally populated and are therefore not accessible to absorption spectroscopy. Examples are levels closely below the dissociation energy, where the vibrating atoms reach very large internuclear distances at their outer turning point.

The accuracy of wavelength measurements is limited by that of the spectrograph or interferometer used for dispersing the LIF spectrum. Higher spectral resolution can be achieved by stimulated emission pumping, where a second tuneable laser L2 is used to induce stimulated emission from the excited level $|f\rangle$ (**Figure 8b**). The transition can be detected by the corresponding decrease of the population $N(k)$, which may be monitored by LIF or by photoionization of level $|k\rangle$.

Double-Resonance Spectroscopy

Double-resonance spectroscopy is based on the simultaneous resonant interaction of two electromagnetic waves,

Figure 7 Doppler-free two-photon spectroscopy of the $5S_{1/2} \leftarrow 3S_{1/2}$ transition of the sodium atom. Reproduced from Cagnac and co-workers.

Figure 8 (a) Laser-induced fluorescence and (b) stimulated emission pumping.

which induce two transitions sharing a common level (**Figure 9**). In the V-type double resonance (**Figure 9a**) this common level of both transitions is the lower level $|i\rangle$ of the two transitions. The laser L1, called the pump laser, depletes the population of level $|i\rangle$ and increases that of $|k\rangle$. If L1 is chopped, the populations N_i and N_k are modulated with opposite phases. The probe laser L2

is tuned through the spectrum of allowed transitions. Each time its wavelength λ_2 coincides with a transition $|i\rangle \rightarrow |m\rangle$ or $|k\rangle \rightarrow |n\rangle$, its absorption will be modulated. This can be monitored either on the transmitted intensity $I_T(L2)$, or with LIF or RTPI (resonant two-photon ionization). Since the starting level, marked by the pump, is known, these optical double resonance

Figure 9 Double-resonance schemes: (a) V-type; (b) Λ -type; (c) stepwise excitation.

signals can be more readily assigned than the much more abundant lines in a conventional absorption spectrum. The OODR (optical-optical double resonance) technique therefore is a very convenient method for facilitating the assignment of complex and perturbed spectra.

The Λ -type OODR scheme (**Figure 9b**) can be regarded as stimulated resonance Raman scattering. It can be performed in cells or in molecular beams and yields Doppler-free signals if the two lasers involved are operated as single-mode lasers. The resonance signal appears when L2 is tuned to resonance $\nu_1 - \nu_2 = (E_i - E_f)/h$. The Λ -type scheme can be used, for instance, to investigate with sub-Doppler resolution the structure and dynamics of levels closely below the dissociation limit. One example is the mixing of *gerade* and *ungerade* singlet and triplet states at large internuclear distances, where the energy differences between the two electronic states becomes comparable to the hyperfine splittings of the atomic dissociation products. In these cases the indirect coupling of the nuclear spins by the electron spins can mix both states. This process may become important in cold atomic clouds kept in magneto-optical traps where collisions between atoms can lead to spin flips, which correspond in the molecular picture to transitions between triplet and singlet states.

The double-resonance scheme of **Figure 9c** corresponds to stepwise excitation, which may be regarded as the special resonance case of two-photon absorption. The first laser populates the excited level $|k\rangle$ and the second laser induces further excitation into high energy levels, such as Rydberg states. They can be monitored by field ionization or photoionization with high efficiency. These Rydberg levels may also be autoionizing levels above the ionization limit, which can be directly detected through the ions. Since all transitions induced by L2 start from the known level $|k\rangle$, their assignment is greatly facilitated. This enables detailed investigation of structure and dynamics of Rydberg levels and their auto-ionization probabilities.

Time-Resolved Electronic Spectroscopy

The development of ultrashort laser pulses down to pulse durations of 5×10^{-15} s has opened access to studies of extremely fast transient phenomena. Examples are the relaxation of electrons in semiconductors after their excitation by a short light pulse. The electrons excited with a definite energy $\hbar\omega$ into the conduction band thermalize within 10^{-13} s by electron-phonon collisions (**Figure 10**). With a much longer decay constant, they recombine with holes in the valence band before they can be excited again by the next pulse. Such time-resolved studies give important information on the limiting processes for the maximum speed of computers.

In molecular physics, elementary processes such as the vibrations of molecules, the formation or breaking of chemical bonds or electronic isomerization processes can now be visualized by femtosecond spectroscopy. This will be illustrated by two examples. The first is concerned with the wavepacket dynamics of vibrating diatomic molecules. The schematic principle is shown in **Figure 11**. The molecule is excited by a short pulse with duration T from its vibrational ground state into vibrational levels of an electronically excited state. If the spectral width $\Delta\nu \approx 1/T$ is large compared to the vibrational spacings, several vibrational levels are simultaneously and coherently excited. This coherent superposition of vibrational wavefunctions produces a vibrational wavepacket in the upper state that moves with the average velocity of the vibrating nuclei towards the outer turning point where it is reflected. When a second laser pulse with a variable time delay Δt brings the excited molecule into a higher electronic state, the transition probability depends on the location of the wavepacket, because the overlap with the vibrational wavefunctions of this higher state depends on the internuclear distance. For the example of **Figure 11**, transitions from the inner turning point produce the molecular ion M^+ plus the ejected electron e^- , which carries away

Figure 10 Thermalization and recombination of electrons after excitation into the energy E within the conduction band in a semi-conductor with a femtosecond laser pulse.

Figure 11 Wavepacket dynamics of a vibrating diatomic molecule.

the excess energy. From the outer turning point, however, the repulsive ion potential can be reached and the molecular ion M^+ dissociates into $A^+ + B$ or $A + B^+$. When the time delay between pump and probe is continuously

Figure 12 Level scheme of the pump-and-probe technique for a dissociating molecule.

increased, the ratio M^+/A^+ , or respectively M^+/B^+ , will show a periodic modulation, where the period reflects the periodic movement of the wavepacket. The important point is that this pump-and-probe technique allows a time resolution on the femtosecond scale, although the detectors may be much slower. With such controlled time delay of femtosecond pulses, the resultant reaction products may be selected, and in such favourable cases channel-selective photochemistry can be realized.

A second example illustrates the dissociation of a molecule following optical excitation into an electronic state with a repulsive potential (**Figure 12**). The dissociating molecule is excited by a second laser pulse into a fluorescing bound state. The wavelength of this second transition depends on the internuclear separation R .

Choosing the wavelength $\lambda(R_1)$, the correct time delay between pump and probe for exciting the fluorescence reflects the time that the dissociating molecule needs to reach R_1 . This method is not restricted to diatomic molecules but has been demonstrated also for polyatomic molecules.

Measurements of lifetimes of excited states of atoms and molecules give direct information on the absolute transition probabilities and are therefore important for many fields in atomic physics, chemistry and astrophysics. Accordingly, several experimental methods have been developed that cover different time domains. In the nanosecond to microsecond range, the delayed coincidence photon counting technique has proved to be very useful. The molecules are excited by a short laser pulse, which also triggers a linear voltage ramp. The first fluorescence photon emitted by the excited molecules produces an output voltage in the photomultiplier that stops the voltage ramp. The output voltage of this time-to-pulse

height converter is proportional to the time delay between the exciting laser pulse and the emission of the fluorescence photon. Measuring many excitation fluorescence cycles yields a voltage pulse height distribution that is stored in a multi-channel analyser (or a computer) and reflects the exponential decay of the excited molecules.

Since the probability per cycle of detecting a fluorescence photon has to be smaller than unity, the cycle frequency should be large and is only limited by the requirement that the time between successive excitation pulses should be larger than the lifetime of the excited molecules. Therefore, mode-locked synchronously pumped cavity-dumped CW dye lasers are ideal excitation sources. For the excitation of higher electronic states, the visible output pulses can be converted into ultraviolet pulses by optical frequency doubling in optically nonlinear crystals.

In the picosecond and femtosecond range, the pump-and-pulse technique is more suitable where the time

Figure 13 Delayed coincidence photon counting: (a) principal scheme; (b) experimental setup for lifetime measurements.

delay between pump and probe can be accurately realized by an optical delay line (**Figure 13**) where one of the laser pulses travels a variable pathlength before it is again superimposed on the pump pulse direction.

Time-resolved investigations have been applied to measurements of fast relaxation processes, such as the primary steps in the visual process or in photosynthesis, or to collision-induced relaxation of excited states in liquids or gases under high pressures.

Introduction

Laser-induced breakdown spectroscopy (LIBS) is a powerful analytical technique that can be used for the detection and characterization of materials. In LIBS, a focused laser beam is used to generate a plasma plume on the surface of solid and liquid samples or inside the sample volume of gases, liquids, and aerosols. Each excited atom in the plasma emits a unique set of spectral lines, particularly in the optical region of the spectrum. Therefore, this optical emission can be collected and analyzed to determine the chemical composition of a sample. A LIBS plasma can be generated as a single event using just one laser pulse or using repetitive laser pulses. As a result, localized microanalysis with lateral and depth profiling information is easily obtained. Remote sensing of materials is also possible with LIBS, since only photons need to come in direct contact with the sample. The ability to perform analyses on samples at a standoff distance is especially important when dealing with hazardous materials, samples located in a dangerous environment, or in physically inaccessible locations.

LIBS has a distinct advantage over many other techniques since little or no sample preparation is needed before analysis, and it can be used for rapid real-time analysis in field operations. Quantitative analytical results can be obtained from LIBS by using conventional (one-element) or multivariate calibration. Recently, calibration-free LIBS analysis has been demonstrated as the semiquantitative determination of elements, based on theoretical plasma models. With LIBS, there are no

specific requirements for the sample to fluoresce, be Raman-active or infrared-sensitive. It is truly a universal technique, where any sample type can yield a LIBS spectrum.

Theory of Laser-Induced Breakdown Spectroscopy

In practice, LIBS is a very simple spectroscopic technique to implement. A high-powered laser beam (commonly 10-ns pulsed infrared 1.06 μm radiation) is focused through a lens to produce a plasma. The emitted light is collected, often through a fiber optic cable, and directed into a spectrometer (**Figure 1**). However, the physics and chemistry of the plasma initiation, formation, lifetime, and decay are very complicated. Much progress has been made in recent years toward elucidating the physics of the plasma generation processes. Studies that have been performed to characterize the LIBS plasma include local thermodynamic equilibrium (LTE) models, hydrodynamic and kinetic models, nonuniform plasmas, and plasmas generated in a vacuum.

There are two main processes that can initiate ionization of atomic and molecular species in laser-induced breakdown. The first is the direct ionization of the sample by multiphoton ionization (MPI), and the second is the inverse bremsstrahlung (IB) absorption processes. In MPI, atoms or molecules undergo simultaneous absorption of sufficient numbers of photons to cause ionization (or the ejection of electrons from the valence to the conduction band, in the case of metals) (eqn [1]).

If ϵ_1 is the ionization potential, then m , the number of photons, must be greater than the integer part of $(\epsilon_1/h\nu + 1)$. MPI is only significant at wavelengths that are shorter than $\sim 1 \mu\text{m}$ and at high laser power, that is, greater than 10^{10} W/cm^2 . When the wavelength is substantially longer than $\sim 1 \mu\text{m}$, it is statistically unlikely for an atom or molecule to absorb enough photons to increase the energy of the neutral above its ionization potential. This process is also important at low pressures, when few collisions are occurring due to the low particle density of the medium.

Figure 1 Schematic diagram of a typical lab bench LIBS setup.

IB processes involve the absorption of a photon by one or more seed electrons present in the focal volume at the beginning of the laser pulse. These initial free electrons may be generated through the presence of cosmic rays, or by the Earth's natural radiation. The first few photons in a laser pulse can also produce seed electrons from dust, negative ions, such as O_2^- , organic vapors, or from atoms and molecules present in the atmosphere via MPI. Seed electrons are not necessary for 'pure' MPI processes.

In IB, the absorption of a photon raises the electron energy to a higher state in the continuum. This process must occur in the vicinity of a heavy particle, such as an atom, ion, or molecule so that momentum is conserved. In normal bremsstrahlung processes, high-energy electrons emit radiation as they slow down upon interacting with a gas or a solid. This term comes from the German words, *bremsen*, which means to slow down, and *strahlung*, which means radiation. Electrons will typically lose energy by rotational and vibrational excitation of neutral molecules, excitation of electronic states, and by attachment of electrons. However, in IB processes, electrons acquire energy from the absorbance of photons and collisions with atoms, ions, and molecules. If the energy of the free electron is greater than the ionization potential of a neutral species, it can ionize a molecule (M) by colliding with it. This produces two lower-energy free electrons, which can gain more energy from the electric field, causing ionization of other neutrals and two more electrons (eqn [2]).

With the increase in the population of ions and electrons in the focal volume, the probability of electron-photon neutral collisions also increases, resulting in electron multiplication and cascade growth. As more and more electrons repeat the process, there is a geometric growth

in the number of free electrons, resulting in cascade ionization. IB processes can be so dramatic that all the species ablated from the surface of the substrate can be ionized causing such an increase in plasma growth that the entire laser pulse can be coupled into the plasma. This results in the plasma becoming so optically opaque that the substrate becomes shielded from the remainder of the laser pulse.

Both MPI and IB absorption can contribute to cascade ionization. The dominant process will depend on the wavelength of the laser radiation, laser intensity, and density of the medium in which the laser breakdown occurs. IB-dominated breakdown is important at high pressures, when collisional effects are strong, and at wavelengths longer than $1 \mu m$. At shorter irradiation wavelengths ($<1 \mu m$) or at low densities of molecules, the possibility of electrons colliding with neutral species is small. Therefore, MPI dominates usually at these shorter wavelengths and in low-density media. Cascade ionization continues throughout the duration of the laser pulse and results in the ionization and dielectric breakdown of gases, vaporized particles, and the creation of a plasma.

Plasma Life Cycle

The plasma generated by a focused laser beam in LIBS has a distinct, time-dependent life cycle. For a plasma to be created, the breakdown threshold must be reached. This breakdown threshold is usually defined qualitatively as the minimum irradiance needed to generate a visible plasma. With the exponential increase in the production of free electrons and ions by IB and MPI processes, the plasma begins to expand from the initial focal volume. Ablated materials, such as particulates, ions, molecules, neutrals, and electrons, are also present

in the plasma that forms at the surface of the sample in solids and liquids. The ionization potential of gases is generally higher than that of liquids and solids, but they too can be readily analyzed by LIBS. Using higher-energy densities, gases can be ionized with a tightly focused laser to produce a plasma in the sample volume. A sonic boom is produced from the initial expansion of the plasma. The compression wave front, or shock wave, emanates from the focal volume of the plasma. The wave front is traveling well above the speed of sound, on the order of 10^5 ms^{-1} . For comparison, the speed of sound in air is $\sim 345 \text{ ms}^{-1}$ at 21°C . As the plasma expands, it continuously emits spectroscopic signals from all constituent components in the sample. When the plasma cools through radiation and other loss mechanisms, the ionized species recombine to form neutral atoms and molecules.

Throughout the lifetime of the plasma, the emission spectrum changes as a function of time. In the earliest phase, there is a strong white light component, which contains little useful spectroscopic information. This continuum light consists mainly of bremsstrahlung and recombination radiation. Recombination radiation is caused by the recombination of free electrons and ions. As stated earlier, bremsstrahlung radiation is caused by the decrease in the translational energy that occurs when ions and electrons slow down upon collision with a gas or solid. This is in contrast to IB processes, which cause cascade ionization during the initial breakdown event.

After the laser pulse, the continuum gradually fades allowing the weaker spectroscopic signals from the elements of interest to be detected. This occurs in a time frame that is much longer than the laser pulse duration, which in a nanosecond laser is on the order of 10 ns. Since the weaker signals only appear as the continuum fades, the collection of the spectroscopic signal of interest should be delayed.

Time parameters in LIBS are important considerations when obtaining emission spectra. At low laser pulse energies, that is, several millijoules, the time delay may need to be less than 1 ns in duration to obtain an optimal signal. With higher laser powers, the delay may be several microseconds. Too short a gate width will not allow enough signal to be processed across the detector. Too long a gate width will allow too much ambient light to enter the detector thus adversely affecting the signal to noise ratio. Optimization of the time delay and gate width should be performed on the individual samples to maximize the relative intensities of the emission lines for the signatures of interest. Sample properties, such as substrate, matrix, and concentration, and experimental conditions such as laser power, wavelength, and pulse width, can all influence the temperature and energy density of the plasma (Figure 2).

LIBS Emission Signal Enhancement – Background Gas Effects

Different background gases are often utilized to enhance the quality and intensity of the LIBS plasma, especially for the analysis of complicated or difficult samples. The use of argon gas is a common technique to effectively enhance the LIBS emission signal. In this method, a steady stream of gas is directed toward the focal volume of the plasma. This increases both the intensity and quality of the signal by displacing the background air and making it easier to generate a plasma. Calculations of electron densities and plasma temperatures of plasmas created in different background gases show that argon produces the highest temperatures and electron densities, followed by ambient air. Helium is associated with the lowest temperatures and densities.

When laser ablation is performed in a vacuum, lower temperatures are attained and lower concentrations of electrons are seen in the plasma volume than in a gaseous environment. Since there is no pressure counteracting free plasma expansion in the vacuum, the expansion rate is increased whereas the cooling rate is decreased as compared to expansion in a gas. This decrease in cooling rate of the excited electrons can be explained by the dominance of elastic collisions. Since cooling is inversely proportional to the mass of the background gas, heavier gases like argon have a less efficient cooling capacity than helium or air. Therefore, using argon will produce higher plasma temperatures with greater electron density than one produced in ambient air or gases with lower atomic masses, like helium. Argon also displaces the nitrogen and oxygen molecules in the air. This effectively eliminates any interference from these molecules in the analysis of species that contain nitrogen and oxygen atoms, including organic compounds.

When argon gas is utilized, a laser-supported detonation (LSD) wave can be observed at the tip of the vapor plume 3 ns after the laser pulse. An LSD wave occurs when a shock wave front, expanding at supersonic speeds, is transmissive enough to allow the incoming laser energy to penetrate the boundary of the plasma and the surrounding atmospheric gases. The shock wave is powerful enough to compress and heat the gases surrounding the plasma, thus allowing for strong optical absorption of the incoming laser radiation. The compression of background gases by the shock wave enhances the conversion of kinetic energy into thermal energy in the vapor plume by slowing the rate of vapor plume expansion. As a result, the vapor plume generated with a background gas of argon continues to increase in temperature and electron number density after the laser pulse ends. The LSD is thought to create an area of high temperature and low gas density above the vapor plume, which allows the expansion of the plume to continue, in

Figure 2 (a) A commercial LIBS instrument (RT100-HP) developed by A3 Technologies, LLC (Aberdeen, MD, USA) and Applied Spectra, Inc. (Fremont, CA, USA). (b) The emission plasma can be seen underneath the focusing objective. (c) A spectrum was taken of the paint used on a (d) toy truck. It clearly shows that the paint was contaminated with lead (Pb).

addition to supplying energy to the plume, which is well after the end of the laser pulse. This contrasts with the behavior of the plasma in helium where the vapor plume electron number density reaches a maximum at the end of the laser pulse. The phenomenological difference between the two gases can be explained as a function of the mass and ionization potential of the two gases. Argon has mass of 40 amu and an ionization potential of 15.759 eV versus 4 amu and 24.587 eV for helium. The smaller atomic mass at helium means that it is less efficient of preventing vapor plume expansion since it creates less drag than the heavier argon atoms. The higher ionization potential also means the background gas is less ionized during laser ablation so no LSD wave occurs. Since there is no LSD wave, more laser energy is absorbed by the vapor plume. As a result, the electron density and temperature of the plume reach a maximum at approximately the center of the pulse width of the laser.

LIBS Emission Signal Enhancement – Double Pulse

The use of double laser pulses is another method that has been used to produce significant enhancements of the LIBS signal. One limitation of the LIBS technique has been its lower sensitivity compared to other spectrometric techniques such as atomic absorption and inductively coupled plasma atomic emission and mass spectrometry (ICP-AES and ICP-MS). Typically, single-pulse nanosecond LIBS has limits of detection in the parts-per-million range whereas other commonly used elemental analysis methods can detect analytes in the parts-per-billion range or lower. The use of double or multiple laser pulses has developed as a strategy to overcome this deficiency. The term, double pulse, is defined as using two laser pulses to produce a LIBS plasma that are separated in time by nanoseconds or microseconds. Since a majority of the laser energy is absorbed by the target sample and vapor plume,

successive laser strikes can be used to reheat the plasma containing the ionized species, causing significant increases in the emissions of the species present in the plume. The first double-pulse experiments were conducted in bulk aqueous solution by two overlapping, laser-induced plasmas. Using this technique, detection limits were improved by orders of magnitude over a single-nanosecond pulse. In a dense medium, like water, the first pulse forms a bubble in the solution, which reduces the plasma quenching of the second pulse. Temperature and signal enhancements seen in double-pulse LIBS are probably due to (1) rarefaction of atmosphere by the first pulse creating a lower-pressure volume where plasma excitation is more efficient and (2) a larger portion of laser energy of the second pulse being absorbed in the analyte containing plasma, instead of being absorbed at the sample surface or in the atmosphere.

There are many variations in the double-pulse method. It has been used in liquids, on liquid surfaces, with solids, gases, and thin films. Different pulse and laser configurations have been studied including the use of different laser wavelengths, energies, pulse widths, and beam geometries. As with argon, the use of double-pulse LIBS can be used to remove atmospheric nitrogen and oxygen from the plasma volume. This allows the analysis of nitrogen- and oxygen-containing compounds to proceed without interference from nitrogen and oxygen atoms in the air. The initial laser pulse displaces the ambient air whereas the emission from the second pulse is used in the analysis of the compound of interest. Of these two enhancement techniques, the double-pulse technique has a major advantage over the use of argon because it can be used in remote or standoff detection applications.

LIBS Reproducibility and Accuracy Enhancement

For analytical purposes, it is desirable that the extracted mass is independent of possible heterogeneity in the sample. Very short pulses can be used, for example, to eliminate the effect of thermalization and heat transfer across the sample. For pulses of ~ 1000 fs and shorter, the duration of the laser pulse is sufficient to heat up only the electrons in the vicinity of the laser-illuminated spot on the sample surface. An explosion-type ejection of these electrons causes simultaneous destruction and ejection of the cold lattice material due to the Coulomb forces. Thus, in the femtosecond mode, the process of instantaneous vaporization and ionization of the sample can be greatly simplified, without inducing heat transfer across the sample and without shielding of the laser irradiation by the plasma plume. Shielding is not relevant when

using femtosecond lasers since the formation of the plasma plume occurs only after the laser pulse has ended. These factors improve significantly the reproducibility of the analysis.

Use of short-wavelength (ultraviolet, UV) lasers provides more efficient and reproducible ablation and hence is more accurate than the infrared lasers. Advantages of the UV irradiation are associated with more efficient absorption in the sample bulk (i.e., smaller losses due to reflection from the surface and less absorption in the plume above the sample surface), as well as a lower number of steps required for MPI as compared to the laser-induced breakdown in the infrared. Because of the higher photon energy, the UV radiation can break lattice bonds even in a single-quantum absorption event.

Ablation by short-pulse UV lasers is a direct and very efficient method of microextraction. Fractionation effects, which can cause the ratios of elements in a plume to differ from the stoichiometry of the sample, are minimized by utilizing this technique. Although fractionation cannot be entirely avoided, ablation with short-pulse UV lasers reduces the difficulties associated with calibration, reproducibility, and accuracy of the analysis.

The elimination of heat transfer and meltdown effects in the femtosecond mode becomes of particular significance for local lateral and layer-by-layer analyses where one must avoid thermal 'mixing' of neighboring areas in the sample. The UV focus spot can be reduced to a smaller size compared to the infrared. However, use of short-wavelength lasers can result in the deterioration of resolution in layer-by-layer analysis.

Standoff (Remote) Detection Using LIBS

One of the advantages of LIBS over other analytical methods is the ability to analyze samples remotely. Samples need not be placed inside the instrument, or even be in the same proximity, for analysis to occur. The only requirements are the abilities to direct photons to the sample and collect the resulting emission spectrum. If a medium is relatively transparent to the laser beam, and the beam is able to strike its intended target with sufficient energy to create an emitting plasma, LIBS analysis is possible. This is extremely important when samples are physically inaccessible, in a hazardous location or when the substance to be analyzed is potentially dangerous (Figure 3).

There are many examples of remote LIBS in the literature. Rapid analysis of metals including Cu, Zn, Al, Ni, Mo, and Pb has been done at moderate distances of 0.5–2.4 m to demonstrate the utility of this technique for identification and sorting purposes in industrial applications. Remote LIBS in combination with specific laser ablation techniques has also been shown to be of great

Figure 3 Schematics of the standoff LIBS system used as a 50-m remote detector of explosive materials in Mojave Desert. The sensor concept and the chemometric identification algorithms were developed and successfully field-tested by A3 Technologies, LLC (Aberdeen, MD, USA) and Applied Spectra, Inc. (Fremont, CA, USA) in collaboration with the US Army Research Laboratory (Aberdeen Proving Ground, MD, USA).

value in the cleaning of cultural heritage objects, such as statues, architectural structures, and other archeological materials.

Since LIBS can be performed remotely and with no part of the instrument coming in direct contact with the specimen, it can be very useful in applications where contamination of equipment is an issue. LIBS has been used with success in spent nuclear fuel reprocessing plants where a laser beam can be introduced into a highly radioactive chamber through leaded glass to analyze both radioactive and nonradioactive deposits coating a dissolver basket. No decontamination of equipment is necessary since the system does not come into physical contact with the highly radioactive surfaces. Other industrial applications include the identification of carbon contamination in molten steel, analysis of mineral melt at 1600 °C, and remote analysis of high-voltage insulators. In summary, remote LIBS is used for process control applications in metallurgy, mineral, and coal industries, and also for environmental control, detection of explosive residues, cultural heritage monitoring, and planetary exploration.

Conclusion

LIBS is a versatile spectroscopic tool that can be easily implemented for the characterization and detection of substances. Since excited atoms of all elements emit in the optical segment of the spectrum, there are no restrictions on the type of samples to be analyzed. LIBS can be used for real-time analysis of materials as a remote or portable system. Little or no sample preparation is required and the technique is sensitive to residues in

concentrations of parts-per-million. Enhancement of the LIBS signal can be accomplished with the use of argon gas that increases the temperature and the electron density of the emission signal. The double-pulse laser technique can also enhance signal quality by reheating the plasma as well as displacing the oxygen and nitrogen present in ambient air. Femtosecond UV laser pulses offer advantages in accuracy and in reproducibility of LIBS spectra due to the elimination of heat transfer, shielding, and fractionation effects. Recent developments in both laser technology and basic understanding of the plasma physics have allowed LIBS to be used reliably and with great sensitivity in a wide variety of analytical applications.

Symbols

A	absorbance
c_p	specific heat capacity
E_λ	energy of an Einstein of wavelength λ
H	transducer response
k	instrumental factor
n	number of moles of absorbed photons
N_A	Avogadro number
N_{ph}	number of incident photons
q	energy released as heat
T	temperature
v_a	sound velocity
V	volume
V_0	volume of illuminated sample
α_i	q_i/E_λ
β	cubic expansion coefficient
Δp	pressure change
ΔV_e	structural volume change per absorbed Einstein
ΔV_r	volume change due to solute–solvent rearrangements
ΔV_{th}	volume change due to radiationless relaxation
κ_S	adiabatic compressibility
κ_T	isothermal compressibility
λ	excitation wavelength
ρ	density
τ_i	lifetime of transient i
Φ_i	quantum yield of step i
φ_i	fractional contribution to volume change of transient i

Introduction

Time-resolved laser-induced optoacoustic spectroscopy (LIOAS) is a sensitive photobaric method for non-destructive probing of materials that monitors the pressure changes induced in a liquid sample after photoexcitation with a pulsed laser. LIOAS delivers information generally not available from optical studies and therefore complements other methods. After excitation, commonly with nanosecond pulsed lasers, the

time evolution of the pressure pulse is monitored by fast piezoelectric transducers frequently located in a plane parallel to the direction of the laser beam (right-angle arrangement). Front-face geometry has also been used, especially with strongly absorbing samples. This article concentrates mainly on the former arrangement.

So far, time-resolved information can be used only in the case of pseudo-first-order reactions, either parallel or sequential, including thermal equilibria, since the LIOAS data analysis has been developed for schemes complying with a time-dependent pressure evolution represented by a sum of single-exponential decays.

Measurement of the heat evolved is used for determination of energy levels of intermediates (including the energy associated with chromophore–solvent interactions), provided that the quantum yields for the reactions are known. Conversely, if the energy level of the intermediates is known from other spectroscopic techniques, the determination of quantum yields is possible, for example for isomerization, charge transfer, fluorescence, intersystem crossing and energy transfer processes.

The structural volume changes are essentially density changes and reflect movements in the chromophore such as photoinduced changes in charge distribution and in the strength of the interactions with solvent molecules. Time-resolved LIOAS data also afford the decay rate constants of the transients, and therefore provide a check for the assignment of the observed events to a particular intermediate. A further identification of the transients involved is offered by the action spectrum of the pressure evolved.

LIOAS is an interesting tool for investigating photo-induced ‘optically silent’ intermediates, i.e. displaying no absorption or emission. A phenomenological approach to the equations is employed here and a description is given of the equipment and data handling as well as a few examples of applications of LIOAS to small molecules. Applications to biological complex systems can be found in the work by Schulenberg and Braslavsky listed in the Further Reading section.

Phenomenological Approach

Pressure pulses in the illuminated sample arise from the volume changes produced by radiationless relaxation

(ΔV_{th}) and structural solute–solvent rearrangements (ΔV_r). Relaxation originates from either nonradiative decay of excited states or release of heat (enthalpy change) in photoinitiated reactions, including the heat involved in the rearrangement of the solvent. The structural volume changes reflect movements of the photoexcited molecules and/or the surrounding solvent in response to such events as dipole moment change, charge transfer, and photo-isomerization. The overall pressure change is given by eqn [1].

$$\Delta p = -\frac{1}{\kappa_T} \left(\frac{\Delta V}{V_0} \right)_T = -\frac{1}{\kappa_T} \left(\frac{\Delta V_{th} + \Delta V_r}{V_0} \right)_T \quad [1]$$

where p is the pressure change, V_0 is the volume of the illuminated sample, κ_T is the isothermal compressibility (see below). The pressure change induces an electrical signal H from the transducer, proportional to the pressure change through an instrumental factor k (eqn [1]):

$$H = k \cdot \Delta p \quad [2]$$

The voltage is given by

$$H = \frac{1}{\kappa_T} \frac{k}{V_0} (\Delta V_{th} + \Delta V_r) = k' (\Delta V_{th} + \Delta V_r) \quad [3]$$

Since the signal is proportional to the number of moles of absorbed photons, n ,

$$n = \frac{N_{ph}}{N_A} (1 - 10^{-A}) \quad [4]$$

where A is the absorbance of the solution at the excitation wavelength λ , N_A is the Avogadro number, and N_{ph} is the number of incident photons, the total signal is given by

$$H^S = k' n \left(\alpha \frac{\beta}{c_p \rho} E_\lambda + \Delta V_e \right) \quad [5]$$

where $E_\lambda = N_A (h.c/\lambda)$ is the energy of an Einstein of wavelength λ , $\alpha = q/E_\lambda$ is the fraction of absorbed energy E_λ released as heat q , $\Delta V_e = \Delta V_r/n$ is the structural volume change per absorbed Einstein, c_p is the specific heat capacity, ρ is the density, and β is the cubic thermal expansion coefficient of the solution [for dilute solutions (<1 mM) these properties are those of the solvent]. To obtain α and ΔV_e , the instrumental constant, k' , must be determined by comparing the signal of the sample with that of a calorimetric reference, i.e. a system that releases all the absorbed energy as heat in a time shorter than the instrumental response. The calorimetric reference and the sample solutions should be measured under identical experimental conditions such as solvent, temperature, excitation wavelength and geometry.

Since the isothermal compressibility κ_T is related to the adiabatic compressibility, κ_S by

$$\kappa_T = \kappa_S + T \frac{\beta^2}{c_p \rho} = \frac{1}{\rho v_a^2} + T \frac{\beta^2}{c_p \rho} \quad [6]$$

(with v_a the sound velocity in the medium) care should be taken to use the proper values of κ_T in eqn [3], especially when determining the thermoelastic parameters using a calorimetric reference in a different solvent. In neat water $\kappa_T = \kappa_S$ and the situation is simpler.

The signal for the calorimetric reference is given ($\alpha = 1$) by

$$H^R = k' n \frac{\beta}{c_p \rho} E_\lambda \quad [7]$$

When permanent products or transient species living much longer (~ 5 times) than the pressure integration time are the only products of the photoreaction, the amplitudes of the LIOAS signals serve to determine the heat and structural volume changes through application of eqn [8] (obtained from the ratio of eqns [7] and [5]) relating the fluence-normalized LIOAS signal amplitudes for sample and reference solutions, H_n^S and H_n^R , respectively:

$$\frac{H_n^S}{H_n^R} = \alpha + \frac{\Delta V_e}{E_\lambda} \frac{c_p \rho}{\beta} \quad [8]$$

For transient species with lifetimes within the pressure integration time, kinetic information is obtained by considering that the signal is a time convolution between the transfer function $H^R(t)$ of the instrument, obtained with the calorimetric reference, and the time derivative $H(t)$, of the time-dependent total volume change:

$$H^S(t) = \int_0^t H^R(t') H(t - t') dt' \quad [9]$$

Numerical reconvolution has been used to retrieve the kinetic, enthalpic and volumetric parameters. Direct deconvolution methods have been developed as well. The reconvolution methods assume a sum of single-exponential decay functions for the time evolution of the pressure:

$$H(t) = \sum_i \frac{\varphi_i}{\tau_i} e^{-t/\tau_i} \quad [10]$$

where τ_i is the lifetime of transient i and φ_i is its fractional contribution to the measured volume change. This assumption bears no implications regarding the mechanism involved, since several mechanisms lead to a function such as eqn [10].

A quadratic approximation to the convolution integral has proved to be the best method for optimizing the

Figure 1 LIOAS signals of benzophenone (S, ---) and 2-hydroxybenzophenone (R, ···) in N₂-bubbled acetonitrile. Fitted curves (F, —) obtained by reconvolution of the reference signal R with single-exponential (left) and two-exponential (right) decay model functions $H(t)$. Residuals and autocorrelation function are given for inspection of the goodness of the fits. Index n corresponds to subindex i in the text.

results. A Levenberg–Marquardt algorithm performing a least-squares minimization is used. The number of transients is successively increased until no further (10–20%) improvements is observed in the value of χ^2 and in the residuals trend. A single-exponential decay did not correctly describe the signal of benzophenone in acetonitrile, whereas the sum of two single-exponential decays yielded a perfect fit (**Figure 1**). Upon addition of a third exponential no significant improvement in χ^2 was observed (not shown).

Up to three lifetimes have been resolved in pulsed photoacoustic spectroscopy experiments, provided that they were separated by at least a factor of 4. In the case of closer values, a strong correlation between amplitudes and lifetimes appears, preventing a reliable recovery of the parameters. Lifetimes below a few nanoseconds are integrated in the prompt response, for which it is only possible to obtain the fractional amplitude.

Lifetimes between a few nanoseconds and some microseconds can readily be deconvoluted. By applying simulations based on a theoretical treatment of the signal, restoration limits have been derived for amplitudes and lifetimes in the case of a sum of two single-exponential decays. The influences of variable geometry, energy distribution and different deconvolution methods, as well as that of the signal-to-noise ratio on the restoration of the amplitudes and lifetimes, have been analysed.

Since a general feature of the microsecond transients is a strong correlation between their lifetime and amplitude, their evaluation is more critical. Simulations show that the front-face geometry in principle covers a broader frequency range than does the perpendicular arrangement at the same signal-to-noise level. However, the polymeric detector used in this scheme has a smaller sensitivity compared to the piezoceramic detectors, which defeats the purpose of a higher signal-to-noise ratio. The high absorbance needed and other technical problems constitute a problem with the front-face geometry.

The fractional amplitudes ϕ_i in eqn [10] contain the heat release q_i and the structural volume change $\Delta V_{r,i}$ of the i th step. Both contributions can be considered additive provided the time evolution of both is the same (eqn [11]). This assumption has been validated in several systems.

$$\phi_i = \alpha_i + \frac{\Delta V_{e,i}}{E_\lambda} \frac{c_p \rho}{\beta}, \quad \alpha_i = \frac{q_i}{E_\lambda}, \quad \Delta V_{e,i} = \Phi_i \Delta V_{r,i} \quad [11]$$

where Φ_i is the quantum yield of step i . q_i is related to the enthalpy of the species produced, including the reorganization energy of the medium and to the value of Φ_i . $\Delta V_{r,i}$ represents the molar structural volume change of the i th step, which includes intrinsic changes in the

chromophore as well as solute–solvent interactions. Equation [8] is thus a particular case of eqn [11] for $i = 1$.

A mechanism needs to be determined for the proper interpretation of φ_i . In the case of a sequential reaction scheme such as depicted in eqn [12],

the amplitudes φ_i^{app} derived from the reconvolution analysis are related to the parameters of the elementary steps (i.e. the weight of each step φ_i and the lifetimes τ_i) by eqns [13]–[15]:

$$\varphi_3 = \frac{(\tau_3 - \tau_1)(\tau_3 - \tau_2)}{\tau_3^2} \varphi_3^{\text{app}} \quad [13]$$

$$\varphi_2 = \frac{(\tau_2 - \tau_1)}{\tau_2} \varphi_2^{\text{app}} + \frac{\tau_2}{\tau_3 - \tau_2} \varphi_3 \quad [14]$$

$$\varphi_1 = \varphi_1^{\text{app}} + \frac{\tau_1}{\tau_2 - \tau_1} \varphi_2 + \frac{\tau_1^2}{(\tau_2 - \tau_1)(\tau_1 - \tau_3)} \varphi_3 \quad [15]$$

It is obvious that for a system with $\tau_3 \gg \tau_2 \gg \tau_1$, the equations simplify and $\varphi_i = \varphi_i^{\text{app}}$.

The equations for the reaction scheme [16], including a thermal equilibrium,

are given by eqns [17]–[19]:

$$\varphi_3 = \frac{1}{k_{23}} \left[\left(k_{23} - \frac{1}{\tau_2} \right) \varphi_2^{\text{app}} + \left(k_{23} - \frac{1}{\tau_3} \right) \varphi_3^{\text{app}} \right] \quad [17]$$

$$\varphi_2 = \frac{1}{k_{23}} \left(\frac{1}{\tau_2} \varphi_2^{\text{app}} + \frac{1}{\tau_3} \varphi_3^{\text{app}} \right) \quad [18]$$

$$\varphi_1 \approx \varphi_1^{\text{app}} \quad [19]$$

Separation of Heat Release and Structural Volume Changes

Separation of the heat dissipation and structural terms in eqn [11] is achieved by measuring the LIOAS signals as a function of the solvent ratio $c_p \rho / \beta$. In aqueous solutions the ratio $c_p \rho / \beta$ depends strongly on temperature (mainly owing to the changes in β). Thus, the separation of the contributions is obtained by performing measurements at various temperatures in a relatively small range (e.g. 8–20 °C). A prerequisite is that the temperature does not significantly affect the kinetics of the various processes. The ratio $(c_p \rho / \beta)_T$ for neat water is obtained from

tabulated values. In particular, $\beta_{\text{water}} = 0$ to 3.9 °C ($T_{\beta=0}$), is positive above and negative below this temperature. At $T_{\beta=0}$, heat release gives rise to no signal. This peculiar feature allows the straightforward assessment of the existence of structural volume changes. For aqueous solutions containing salts or other additives at millimolar concentrations or higher, $(c_p \rho / \beta)_T$ and $T_{\beta=0}$ must be determined by comparison of the signal obtained for a calorimetric reference in the solvent of interest and in water.

The precision of the recovered slope of plots with eqn [11], $\Delta V_{e,i} / E_{\lambda}$, is generally good, whereas the intercept α_i is affected by larger errors. In case the main goal is the determination of the structural volume change, a two-temperature method may be applied. Essentially, the LIOAS wave is measured for the sample at $T_{\beta=0}$ and at a slightly higher temperature $T_{\beta \neq 0}$ for which $\beta \neq 0$. The parameters $\Delta V_{e,i} / E_{\lambda}$ and α_i are then calculated with eqns [20] and [21]:

$$\Delta V_{e,i} = \varphi_i(T_{\beta=0}) \left(\frac{\beta}{c_p \rho} \right) E_{\lambda} \quad [20]$$

$$\alpha_i = \varphi_i(T_{\beta \neq 0}) - \varphi_i(T_{\beta=0}) \quad [21]$$

These equations hold only for values of $T_{\beta=0}$ and $T_{\beta \neq 0}$ that are near to each other, such that the rise time of the LIOAS signal and the compressibility of the solution are similar. The signal of the reference at $T_{\beta \neq 0}$ is used together with that of the sample at $T_{\beta=0}$ and at $T_{\beta \neq 0}$ to obtain the values of $\varphi_i(T_{\beta=0})$ and $\varphi_i(T_{\beta \neq 0})$. A time shift of the sample waveform with respect to the reference waveform at $T_{\beta \neq 0}$ is necessary to compensate for the change in the speed of sound, which leads to a slightly different arrival time at both temperatures. Thermal instability of the sample holder and trigger arrival fluctuations make the shifting an important option in the fitting routines.

The temperature dependence of the $c_p \rho / \beta$ ratio in organic solvents is poor, rendering the above procedures inapplicable in these solvents. An alternative approach has been used that relies on the determination of the LIOAS signals in a series of homologous solvents such as linear alkanes, cycloalkanes, or, alternatively, in solvent mixtures. This procedure is valid provided that no significant perturbations are introduced in the photophysics and photochemistry of the solute and that the solvation enthalpy and structural volume change do not vary with change of solvent. These are strong assumptions that need verification in each case.

Calorimetric Calculations

The heat released in each step, q_i , is interpreted in terms of enthalpy changes by using the energy balance

$$E_{\lambda} = \Phi_f E_f + \sum_i q_i + E_{\text{stored}} \quad [22]$$

where the input energy, E_{λ} , is equal to the sum of the energy released as emission (e.g. fluorescence; Φ_f and E_f are the quantum yield and energy constant of the emitting state) and the heat dissipated (changes in the states' energy content plus energy associated with solute–solvent interactions) in each of the steps. E_{stored} represents the total energy trapped in species living much longer than the pressure-integration time of the experiment. Analysis of the calorimetric information requires knowledge of the reaction scheme and the parameters associated with the process such as quantum yields and energy levels derived, for example, from optical measurements.

Instrumentation

Figure 2 shows a typical LIOAS setup. A calibrated beam splitter guides a fraction of each laser pulse to an energy meter for normalization purposes. The sample holder contains a normal quartz cuvette inside a thermostated metal block.

The unfocused beam is shaped by passing it through a slit (200 μm –2 mm) placed in front of the cuvette. With fast transducers, the beam size determines the rise time of signal and, therefore, the time resolution. The piezoelectric transducer is pressed against the cuvette (Figure 3).

The higher sensitivity of the slit-shaping geometry allows the use of the lower photon densities. The transducer is either a crystal such as lead zirconate titanate (PZT) or a film such as β -poly(vinylidene difluoride) (PVF). PZT is more sensitive, whereas the wide band PVF films provide a better temporal resolution. PZTs are generally resonant, damped transducers, the highest usable peak frequencies being about 100 MHz, with typical values around 1 MHz. Very high impedance is common to both types of transducers. After impedance matching, the electrical signal is fed into a high gain amplifier (typically $\times 100$ and of bandwidth compatible with the transducer in use). The amplified signal is stored by a transient recorder.

Applications to Selected Systems

The Triplet State of a Porphyrin (TPPS₄)

The high triplet yield of porphyrins is important in a number of photobiological and photochemical problems, for example in the photodestruction of the photosynthetic apparatus and in photodynamic therapy (PDT). 5,10,15,20-Tetrakis(4-sulfonatophenyl)porphyrin (TPPS₄) is a water-soluble porphyrin derivative used as a standard compound in PDT research. The LIOAS signal upon excitation of TPPS₄ in 10 mM Tris buffer (pH 7.8) at 30 °C in the presence of O₂ (Figure 4) was fitted with a sum of three exponential decays (eqn [10]), corresponding to the porphyrin triplet formation within a few nanoseconds, its decay (lifetime of about 2 μs) and the decay of singlet

molecular oxygen ($\text{O}_2(^1\Delta_g)$, lifetime 3–3.5 μs) formed by energy transfer from triplet TPPS₄ to ground-state O₂ (see Figure 6). Measurements at various temperatures (5–30 °C) and in D₂O showed that the triplet formation and decay exhibit large structural volume changes, whereas O₂ ($^1\Delta_g$) does not.

Owing to the closeness of the values of the triplet and the O₂ ($^1\Delta_g$) lifetimes, it was not possible to fit the signal with a three-exponential function in the whole temperature range. A sum of two single-exponential functions was used instead. The slow component (fixed at 2.5 μs) represented the triplet plus the O₂ ($^1\Delta_g$) decay. The plot of the parameters φ_i (eqn [12]) vs $c_p\rho/\beta$ (Figure 5) shows that triplet formation (φ_1) is accompanied by a contraction $\Delta V_{r,1} = -10 \pm 3 \text{ mL mol}^{-1}$, whereas triplet decay (φ_2) is concomitant with an expansion of similar magnitude, $\Delta V_{r,2} = 10 \pm 3 \text{ mL mol}^{-1}$. This structural

Figure 4 Fitted curves (F, —) obtained from deconvolution of the LIOAS signal of TPPS₄ (S, ---) in air-saturated 10 mM Tris buffer (pH 7.8) at 303 K with two-exponential (right) and three-exponential (left) decay model functions. The reference compound was bromocresol purple (R, ····). Residuals and autocorrelation function are given for inspection of the goodness of the fits. Index n corresponds subindex i in the text.

Figure 5 Plot of ϕ_1 ($\tau_1 < 10$ ns) and ϕ_2 (τ_2 fixed at 2.5 μ s) as a function of $c_p \rho / \beta$ (eqn [11]) for TPPS₄ in air-saturated 10 mM Tris buffer (pH 7.8) with bromocresol purple as a calorimetric reference. volume change indicates that triplet TPPS₄ has a stronger hydrogen-binding ability than the ground state, inducing a contraction of the surrounding hydration shell. Further LIOAS experiments with TPPS₄ and other

mesosubstituted porphyrins enabled attribution of the structural volume changes to the photoinduced changes in the interactions with water (via hydrogen bonds) of the N atoms in the pyrrol units of the porphyrin ring.

The molar energy absorbed by the system, E_λ , is dissipated throughout the four possible processes undergone by the excited molecules, i.e. fluorescence, prompt heat by vibrational relaxation and internal conversion ($S_1 \rightarrow S_0$), intersystem crossing ($S_1 \rightarrow T_1$; $T_1 \rightarrow S_0$), loss during energy transfer to molecular oxygen, and stored heat (eqn [23]). Phosphorescence from TPPS₄ triplet and from $O_2(^1\Delta_g)$ are known to have yields below 10^{-3} and were neglected.

$$E_\lambda = \Phi_f \cdot E_f + q_1 + q_2 + q_3 \quad [23]$$

$$\begin{aligned} q_1 &= E_\lambda - E_S + \Phi_f(E_S - E_f) \\ &\quad + (1 - \Phi_f - \Phi_T)E_S + \Phi_T(E_S - E_T) \\ q_2 &= (\Phi_T - \Phi_\Delta)E_T + \Phi_\Delta(E_T - E_\Delta) \\ q_3 &= \Phi_\Delta E_\Delta \end{aligned}$$

The heat released during the formation of the triplet state as calculated from the intercept of the plot

Figure 6 Term diagram for the photophysical processes occurring after excitation of TPPS₄ in aerated aqueous solutions. Double arrows denote light absorption and radiative decay process not detectable with LIOAS. Single full, dashed and broken arrows denote radiationless processes contributing to φ_1 , φ_2 , and φ_3 . Subscript fl denotes fluorescence, ic, internal conversion, isc, intersystem crossing, ph, phosphorescence, $K_q[O_2]$, is the quenching constant of triplet T_1 by oxygen.

(Figure 5, eqn [12]), $\alpha_1 = 0.58 \pm 0.05$, was used to determine the triplet quantum yield $\Phi_T = 0.61$, by using the literature values $E_f = 174 \text{ kJ mol}^{-1}$, $E_S = E_{0-0} = 186 \text{ kJ mol}^{-1}$, $\Phi_f = 0.06$, and $E_T = 139 \text{ kJ mol}^{-1}$ (at 77 K) and a simple energy balance equation (see Figure 6 for the meaning of the symbols). Alternatively, the average $\Phi_T = 0.67$ (from literature) can be used to calculate $E_T = 126 \text{ kJ mol}^{-1}$, which is the first report of a triplet energy value for this porphyrin at room temperature.

Porphyrin to Quinone Electron Transfer

The interest in understanding the molecular basis of the biologically fundamental electron transfer process from the chlorophyll derivative pheophytin to a quinone in photosynthesis has led to the development of a large number of models, such as synthetic systems with porphyrin derivatives as donor and quinones as acceptor. Feitelson and Mauzerall demonstrated the power of LIOAS for the determination of rate constants, quantum yields and structural volume changes in solution of such systems. The triplet yields and electron transfer efficiencies were determined in various solvents. Electrostriction after formation of the ion pair was suggested as the source of structural volume change leading to a contraction in the charge-separated state. Electrostriction describes the contraction of the solvent around a charged molecule. The magnitude of the effect is inversely proportional to the radius of the molecule and to the dielectric constant of the solution. A problem in this connection is that the

theoretically derived values using a solvent continuum model are far too small compared to the measured effects. This problem needs further attention.

The structural volume changes for triplet formation of metal-free uroporphyrin ($-0.45 \text{ cm}^3 \text{ mol}^{-1}$) and of its zinc complex ($-1.1 \text{ cm}^3 \text{ mol}^{-1}$), as well as the structural volume changes due to electrostriction after electron transfer from Zn-uroporphyrin to a quinone ($-4.4 \text{ cm}^3 \text{ mol}^{-1}$), were estimated in aqueous solutions. The entropy change due to ion formation was then estimated as $-202 \text{ kJ mol}^{-1} \text{ K}$ for the latter system.

Ru(II) Bipyridyl Complexes

Ruthenium(II) bipyridyl (bpy) complexes constitute interesting compounds for LIOAS studies since their photophysical parameters are known and their transient lifetimes are within the integration time of the LIOAS experiment. In all these complexes, the metal-to-ligand charge transfer (MLCT) state in aqueous solution is formed with unity quantum yield and relaxes within 100–600 ns (depending on the complex) to the ground state.

In particular, the structural volume changes for the formation of the MLCT state of $\text{Ru}(\text{bpy})(\text{CN})_4^{2-}$, $\text{Ru}(\text{bpy})(\text{CN})_3(\text{CNCH}_3)^-$, $\text{Ru}(\text{bpy})_2(\text{CN})_2$, and $\text{Ru}(\text{bpy})_3^{2+}$ of 15, 10, 5, and $-3.5 \text{ cm}^3 \text{ mol}^{-1}$ correlate with the number of CN groups. Thus, the structural volume changes are interpreted as expansion of the strong second-sphere donor–acceptor interaction of the CN groups with water after weakening of the π backbone in the Lewis-base cyano substituents concomitant with the ruthenium photo-oxidation. The complex $\text{Ru}(\text{bpy})_3^{2+}$ (with no CN groups) shows a small contraction of $-3.5 \text{ cm}^3 \text{ mol}^{-1}$ due to intrinsic Ru–bpy bond shortening. The lifetimes derived by deconvolution were similar to those obtained by emission. (Figure 7).

For the cyano-Ru(II) complexes in neat water, the heats derived from the intercepts of plots with eqn [11] afforded values of the energy content of the MLCT states similar to those derived from emission data. Both for intra- and intermolecular electron transfer reactions of cyano-Ru(II) complexes in aqueous solutions in the presence of salts, the structural volume change correlates with the entropy change of the reaction. An enthalpy–entropy compensation effect occurs upon perturbation of the water structure by the addition of the salts.

$\text{Ru}(\text{bpy})(\text{CN})_4$ inside the water pools of sodium bis (2-ethylhexyl)sulfo-succinate (AOT) reverse micelles with a large water pool inside the micelle showed a structural volume change similar to that in neat water, whereas in micelles with a small water pool the structural volume changes were smaller.

These findings support the model of a change in the CN–water interaction as the origin of the expansion

Figure 7 Structural volume change (ΔV_r) associated with the formation of the MLCT state of $\text{Ru}(\text{bpy})(\text{CN})_4^{2-}$ and its decay (lifetime $\tau_2 = \tau_{\text{MLCT}}$) in 0.1 M AOT-water-*n*-alkane reverse micelles at various values of $R = [\text{water}]/[\text{AOT}]$. upon MLCT formation. In a large water pool $\text{Ru}(\text{bpy})(\text{CN})_4$ interacts with free water (i.e. the $\text{Ru}(\text{bpy})(\text{CN})_4$ environment is similar to that in neat water), whereas in a small water pool the interactions involve ‘bound water’ (water molecules interacting with the charged detergent molecules), and the expansion is impaired and reduced.

Proton Transfer and the Reaction Volume for Water Formation

The structural volume changes photoinduced in solution during the proton transfer between *o*-nitro-benzaldehyde and hydroxyls in water have been studied by means of LIOAS. Upon photoexcitation, *o*-nitrobenzaldehyde is converted to *o*-nitrosobenzoic acid and protons are detached with a quantum yield of about 0.4. At pH around and below neutrality, solvation of the charges is accompanied by a fast, subresolution contraction of the medium of approximately $-5.2 \pm 0.4 \text{ cm}^3 \text{ mol}^{-1}$. This contraction is at least qualitatively accountable for on the basis of the electrostrictive effects described by the Drude–Nernst equation, considering the negative charge localized on the carboxylic oxygen atom of *o*-nitrosobenzoic acid and using the molar volume of the proton in water. At pH > 9, the reaction with hydroxyls becomes relevant and the formation of water molecules produces an expansion of $24.5 \pm 0.4 \text{ cm}^3 \text{ mol}^{-1}$. The plot of the quenching rate constant (k_q , **Figure 8**), derived from LIOAS data vs the concentration of hydroxyls is linear with a slope of $(4.9 \pm 0.4) \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$, indicating that the process obeys pseudo-first-order kinetics.

J_0	photon flux density
k_i	vibrational relaxation rate constant
$[M_i]$	concentration of the i th gas-relaxator
N_a, N_b, N_c	components of N
N_{min}	concentrational sensitivity
$^2P_{3/2}, ^2P_{1/2}$	Cl atomic states
S_a, S_b, S_c, S_z	projections of S
S_p	Poynting vector
v	vibrational quantum number
W_e, x_e	parameters of vibrational Hamiltonian
γ	parameter of spin–rotational term H_{sr}

γ_{min}	sensitivity in cm^{-1} units
$\Delta_N, \Delta_{\text{NK}}, \Delta_K, \delta_N$	centrifugal constants of asymmetric rotor
δ_K	parameter of spin–spin term H_{ss}
λ	components of spin–rotational tensor
$\varepsilon_{aa}, \varepsilon_{bb}, \varepsilon_{cc}$	Bohr magneton
$\mu_0 = e\hbar/2mc$	cross section of the transition
σ	decay time for the saturation kinetics
τ	

Laser magnetic resonance (LMR) is a sensitive technique for studying rotational, vibrational–rotational, or electronic Zeeman spectra of paramagnetic atoms and molecules, using fixed-frequency infrared lasers. High resolution and sensitivity are important characteristics of LMR. In a pioneering experiment in 1968, Evenson and his coworkers succeeded in demonstrating the feasibility of this technique when they detected a rotational transition of O_2 using a HCN laser. Several years later, LMR was extended to the mid-infrared by using CO and CO_2 lasers with similar success. Since then, much of the increase in understanding of the structure and properties of short-lived paramagnetic molecules has come from the application of LMR. The method has allowed the detection of more than 100 free radicals, including elusive species such as HO_2 , CH_2 , FO , and $\text{Cl}(^2P_{1/2})$, which cannot easily be detected by other means. The high sensitivity and versatility of LMR have resulted in numerous applications of the method to chemical kinetics.

Theory of LMR

Atoms

As a simple illustration let us consider the LMR spectra of Cl atoms. The energy-level diagram at the top of **Figure 1** shows the Zeeman effect in Cl atoms.

In a magnetic field, the $|J, I, F\rangle$ levels of the atom split into components labelled by M_J and M_F quantum numbers (here $F = J + I = L + S + I$). The magnetic field is swept, and at suitable values of the field, the frequencies of the transitions $|J, M_J, M_F\rangle \rightarrow \langle J', M_J', M_F'|$ come into coincidence with the frequency of a

Figure 1 Top: Zeeman effect in ^{35}Cl atoms. All sublevels are labelled by M_F values. The lower $^2P_{3/2}$ state is represented by solid lines. Upper $^2P_{1/2}$ state (dashed lines) is downshifted by an amount of the laser photon energy. Intersections of solid and dashed lines with $\Delta M_F = \pm 1$ (open circles) or with $\Delta M_F = 0$ (solid circles) represent possible LMR transitions. Bottom: LMR spectra of Cl atoms (both ^{35}Cl and ^{37}Cl).

fixed-frequency laser. These resonances result in a decrease in detected laser power. In practice, a small modulation (up to 50 G) is added to the magnetic field, and the change in transmitted laser power is recorded as a first derivative signal by processing the detector output in a phase-sensitive amplifier.

LMR spectra of Cl atoms are shown at the bottom of **Figure 1**. Note that $^2P_{3/2} \rightarrow ^2P_{1/2}$ magnetic dipole transitions with $\Delta M_F = \pm 1$ and $\Delta M_F = 0$ occur at $E \perp B$ and $E \parallel B$ polarizations, respectively; here E is the electric field of the laser radiation and B is the magnetic field of the electromagnet.

The Hamiltonian may be written as

$$H = A_{\text{so}}LS + H_{\text{hfs}}(a, b, \mathbf{J}, \mathbf{I}) + \mu_0(g_J\mathbf{J}B + g_I\mathbf{I}B)$$

where H_{hfs} is the hyperfine interaction operator, A_{so} a spin-orbit interaction constant, a and b hyperfine constants, $\mu_0 = e\hbar/2mc$ the Bohr magneton, and g_J and g_I are electron and nuclear g -factors. All these atomic constants can be obtained from the analysis of LMR spectra; the precise values for A_{so} have been determined in this way for the first time.

Diatomic Radicals

A more common application is the measurement of LMR spectra of linear radicals with both spin and orbital angular momentum (SnH, NiH, GeH, CH, SD, SeH, etc.). The effective Hamiltonian is a summation of spin-orbit (H_{so}), vibrational (H_v), rotational (H_{rot}), spin-rotational (H_{sr}), spin-spin (H_{ss}), lambda-doubling (H_{ld}), hyperfine (H_{hfs}), and Zeeman (H_z) terms:

$$H = H_{so} + H_v + H_{rot} + H_{sr} + H_{ss} + H_{ld} + H_{hfs} + H_z \quad [1]$$

The choice of significant terms and representation of the terms are determined by the particular type of radical. Some usual representations are presented below.

$$H_{so} = A_{so}LS$$

$$H_v = \hbar\omega_e(v + 1/2) - \omega_e x_e \hbar(v + 1/2)^2$$

$$H_{rot} = B_v N^2 - D_v N^4$$

$$H_{sr} = \gamma NS$$

$$H_{ss} = \frac{2}{3}\lambda(3S_z^2 - S^2)$$

$$H_z = \mu_0(g_s S + g_L L + g_r N)B$$

Here v denotes the vibrational quantum number and $N = J - L - S$ is the nuclear rotational angular momentum. Centrifugal corrections to some parameters are often used as well as a tensor expression for H_z .

Polyatomic Radicals

The most often encountered type of radical observed by LMR is the three-atomic asymmetric-top radical, such as NH_2 , PH_2 , HCO , HO_2 , so, Hund's case (b). In this case, the Hamiltonian eqn [1] is used. Without spin-orbit and lambda-doubling terms, H_{rot} , H_{ss} , and H_{sr} are usually expressed as:

$$H_{rot} = A_v N_a^2 + B_v N_b^2 + C_v N_c^2 + H_{cd}(N, \Delta_N, \Delta_{NK}, \Delta_K, \delta_N, \delta_K)$$

$$H_{ss} = \frac{1}{3}D_v(2S_a^2 - S_b^2 - S_c^2) + E_v(S_b^2 - S_c^2)$$

$$H_{sr} = \varepsilon_{aa}N_a S_a + \varepsilon_{bb}N_b S_b + \varepsilon_{cc}N_c S_c$$

where H_{cd} is the Watson's centrifugal distortion operator; the molecule-fixed components of N , S , and ε are labelled by a , b , and c .

Finally, note that the representation of the Hamiltonian is very dependent on the particular radical. Some terms are often omitted, and some new ones are added. For example, Jahn-Teller distortion should be taken into account for symmetric top radicals, such as CH_3O and SiH_3 .

The LMR detection of polyatomic radicals with heavy (not hydrogen) atoms is hindered for several reasons: (1) the

population of the lower state is low, and it decreases with rotational partition function; (2) Zeeman splitting is small, and it decreases both with moments of inertia and with rotational quantum numbers of the radical; hence, LMR spectra are observable only at low magnetic fields because of a weak coupling of S with N . Moreover, the spectra are often unresolved because of a large number of components.

An important exception was found for the first time by Uehara and Hakuta, who have observed high-field spectra in the v_1 band of ClO_2 in spite of its small spin-orbit interaction. Later, similar high-field far-infrared LMR spectra of FO_2 , $ClSO$, FSO , and NF_2 were detected. These spectra were assigned to transitions induced by avoided crossings between Zeeman levels having the same value of M_J but differing by one in N . This type of transition offers a new means to study radicals which might otherwise be inaccessible to the LMR technique.

LMR Spectrometer

Basic Features

The essential features of an LMR spectrometer are illustrated schematically in **Figure 2**, which shows three of the most commonly encountered experimental configurations.

A conventional intracavity LMR spectrometer is shown in **Figure 2(a)**. Placing a free-radical absorption cell inside the laser cavity results in a gain in sensitivity due to multipassing of the laser radiation. A further sensibility gain may also be obtained when the modulation frequency is close to the frequency of the laser intensity relaxation oscillations. Another benefit of the intracavity configuration is that it favours the observation of saturation Lamb dips. This is especially important in the mid-infrared region, where Doppler widths are greater and the high resolution of saturation spectroscopy is needed more. The laser power is coupled out by the zeroth order of the grating and is detected by a photoresistor. Coupling through the hole in one of the mirrors or by a variable coupler inserted into the laser cavity is also used.

An intracavity LMR spectrometer based on an optically pumped laser is shown in **Figure 2(b)**. The only difference is the change of the CO (or CO_2) laser in **Figure 2(a)** by an optically pumped laser. The pump radiation is multiply reflected between two metallic-coated flats parallel to the far-infrared laser axis. Longitudinal pumping in which the pump radiation is introduced along the laser axis through a hole in one of the far-infrared laser mirrors is also employed. The cavity is divided by a beam splitter (e.g., thin polypropylene).

Figure 2(c) gives the block diagram for the Faraday LMR setup, in which there is an extracavity arrangement and detection of paramagnetic species is via their

Figure 2 Schematic representation of an LMR spectrometer: (a) mid-infrared intracavity arrangement, (b) far-infrared intracavity arrangement with optically pumped laser, (c) mid-infrared Faraday extracavity arrangement. EM = electromagnet pole, MC = modulation coil, G = diffraction grating, PR = photoresistor, M = mirror, P_x and P_y = polarizers.

polarization effects. The laser light propagates along the z -axis, which coincides with the magnetic field direction. The polarization, determined by the polarizer P_x points along the x -axis and the polarizer P_y points along the y -axis. The multipass absorption cell is placed between these crossed polarizers. The absorbing radicals produce a change in the polarization; this effect is used for sensitive detection of the radicals.

In essence, the Faraday arrangement is extracavity LMR with two crossed polarizers. These polarizers reduce the laser power by a large factor and the LMR signal by the square of that factor. Hence, the signal-to-noise ratio for the Faraday arrangement is significantly better (more than two orders of magnitude) than that for conventional extracavity LMR.

Note that time resolution of the intracavity configurations is determined by the medium of the laser: it is usually $\sim 2\text{--}4\text{ }\mu\text{s}$; the time resolution of the Faraday arrangement is considerably better.

The Faraday configuration requires the magnetic field of the electromagnet (solenoid) to be parallel to the Poynting vector, $\mathbf{B} \parallel \mathbf{S}_p$; an alternative (Voigt) configuration is proposed in which $\mathbf{B} \perp \mathbf{S}_p$ and a polarization angle relative to $\mathbf{B}$ is 45° . Although the Voigt configuration is expected to have similar sensitivity to that of Faraday LMR, it is rarely encountered.

Usually, the configurations in **Figure 2(a)** and **2(c)** are used in mid-infrared spectroscopy. The configuration in **Figure 2(b)** is used in far-infrared spectroscopy only. In intracavity configurations, the polarization of the laser

with respect to the magnetic field is determined by the intracavity beam splitter in **Figure 2(b)** or by windows in **Figure 2(a)** set at Brewster's angle. The splitter (or the windows) are rotatable about the laser axis so the polarization can be rotated. When the electric vector of the laser lies perpendicular to the magnetic field, $E \perp B$, then $\Delta M_J = \pm 1$ (σ) electric dipole transitions are induced; the $\Delta M_J = 0$ (π) transitions appear with parallel polarization, $E \parallel B$. Note that the latter case is impossible in Faraday LMR.

Infrared Lasers

The first far-infrared LMR spectra were recorded by using HCN, H₂O, and D₂O lasers. Since then, optically pumped lasers are usually used with a line-tunable continuous-wave CO₂ laser as a light source. By use of these lasers, over 1000 laser frequencies are available in the far-infrared region (30–1200 μm); some 500 have been used in LMR.

In medium-infrared, most of the radical spectra are observed with CO (1200–2000 cm^{-1}) and CO₂ (875–1110 cm^{-1}) lasers. In the former case, the spectral region is now strongly extended by using a CO-overtone laser which provides 200 ($\Delta v = 2$) transitions in the region of 2500–3500 cm^{-1} . In the latter case, a great increase in capacity of LMR (several hundreds of lines) was attained by using ¹³C¹⁶O₂, ¹³C¹⁸O₂, ¹³C¹⁶O¹⁸O, and C¹⁸O₂ isotope modifications; an N₂O laser has also been used.

A colour centre laser (2–4 μm) and spin-flip Raman laser (which consists of an InSb crystal pumped by a CO laser) have also been employed.

Infrared Detectors

he first far-infrared LMR spectra were recorded by using Golay cells. These have the advantage of room temperature operation and are easy to use, but their response is slow and hence only low modulation frequencies (approximately 10–100 Hz) can be used. A further gain in sensitivity was realized by use of a helium-cooled Ge bolometer: the much faster response of the bolometer allows much higher modulation frequencies (~ 1 kHz), and this, together with the lower noise equivalent power, means that the sensitivity is limited mainly by inherent noise in the laser source. By far the most commonly encountered far-infrared detectors are helium-cooled photoresistors (Ge:B, Ge:In, Ge:Ga, Ge:As, In:Sb, etc.); modulation frequencies of up to hundreds of kilohertz can be used. Use of superconducting magnets to tune the energy levels is also possible.

In mid-infrared, the most commonly used photoresistors are Ge:Au (77 K), Ge:Hg (53 K), Ge:(Zn, Sb) (64 K), and Hg:Cd:Te (77 K) for CO₂ laser output and Ge:Ga (77 K), In:Sb (77 K), and Hg:Cd:Te (77 K) for CO laser output.

In general, the main noise source is the laser rather than the photoresistor. However, in the mid-infrared region, attenuation of laser light is often required since detectors are easily saturated by laser light. For example, for the In:Sb (77 K) detector saturation starts near 1 mW, whereas typical CO laser output power reaches 1 W. Note that in Faraday and Voigt LMR arrangements, the saturation is absent.

Modulation

The modulation frequency f is determined as a compromise between two factors. First, at low frequencies the noise of the LMR spectrometer increases due to vibrations of the spectrometer. Second, the modulation amplitude decreases inversely with the square root of f at a fixed power of the generator for modulation coils. Finally, for extracavity LMR the best frequency is 15–20 kHz. For intracavity LMR spectrometers, a gain of sensibility can be obtained when the modulation frequency is close to the frequency of the laser intensity relaxation oscillations (50–150 kHz).

A simple method to improve the sensitivity of LMR is to increase the integration time constant of the lock-in amplifier. However, the long-term instability of the LMR spectrometer usually makes useless time constants larger than 3 s. This problem can be solved by using double modulation. The magnetic field is modulated at high (~ 100 kHz) and low (~ 2 Hz) frequencies. The high-frequency signal is demodulated by a phase-sensitive lock-in amplifier. The resulting low-frequency output of the lock-in is again demodulated by another phase-sensitive lock-in. As a result, the effective time constant of the system is ~ 200 s and the LMR sensitivity increases considerably. Note that the best peak-to-peak amplitude of the low-frequency modulation is equal to the spectral line width. The drawback of this double modulation system is the slow response.

Intracavity systems are very sensitive to acoustic cross talk between the modulation unit and the laser resonator, thus increasing the noise just at the modulation frequency f . Hence another method of improving the sensitivity of intracavity LMR is to use a lock-in detector at $2f$ (the second harmonic), where the noise is considerably smaller. In some cases, this change can increase the signal-to-noise ratio of LMR.

Preparation of Radicals

The great majority of radicals studied so far by LMR have been generated by atom–molecule reactions in the gas phase, using discharge-flow techniques or by pumping the products of a microwave discharge rapidly into the sample region of the spectrometer. In addition, a time-resolved arrangement allows generation of radicals either directly by UV photolysis (or multiphoton

dissociation) or by the reactions of appropriate molecules with the species prepared photolytically.

Detection of Molecular Ions

Molecular ions (DCI^+ , DBr^+ , etc.) are generated by discharge-flow techniques. Two difficulties arise in experiments with intracavity LMR detection of these ions. First is the rapid deflection of the ions to the reactor walls in the magnetic field of the electromagnet; the second is the very high noise of a DC discharge situated inside the laser cavity. These problems have been solved by using the Faraday extracavity LMR arrangement, which does not suffer to the same extent from modulation pickup via discharge plasma as the intracavity arrangement. In the Faraday arrangement the discharge is stable, since the magnetic field of the solenoid and the electric field of the discharge are collinear.

An additional advantage of this arrangement is the possibility of tracing hot-band transitions not only for open-shell ions but also for free radicals.

Sensitivity of LMR; Comparison with EPR

The technique of LMR is very similar to other magnetic resonance methods such as EPR and NMR. Whereas NMR uses radiofrequency radiation to produce transitions between nuclear spin levels and EPR uses microwave radiation to produce transitions between electron spin levels, LMR uses radiation of a laser to produce transitions between rotational (far-infrared) or vibrational-rotational (mid-infrared) levels in paramagnetic molecules. Note that the sensitivity $\gamma_{\min}$ is nearly equal for EPR and LMR: $\gamma_{\min} \simeq 10^{-10}$ – 10^{-9} cm^{-1} . The concentration sensitivity is given by

$$N_{\min} = \frac{\gamma_{\min}}{\sigma d}$$

where d is the difference of relative populations of the upper and lower levels and σ is the cross section of the transition. The superiority of LMR over EPR in sensitivity is determined by the d factor (two to three orders of magnitude) and by the cross section σ , which is proportional to the transition frequency. The factor in favour of EPR is the high Q -factor of an EPR resonator. When EPR is compared with mid-infrared LMR, an additional factor in favour of EPR is the dipole transition matrix element, which is an order of magnitude higher for rotational transitions in radicals than that for vibrational-rotational transitions. In general, LMR is much more sensitive than EPR.

The sensitivities of far-infrared intracavity LMR and mid-infrared Faraday LMR are as high as that of laser-induced fluorescence (LIF); the sensitivity of mid-infrared intracavity LMR is usually one order of

Table 1 Typical sensitivities of LMR and EPR

Radical	Laser	Wavelength (μm)	Sensitivity (cm^{-3})
Cl	CO_2	11.3	2(9) ^a
	CH_3OD	145.7	1(10)

^a $a(b) = a \times 10^b$.

magnitude less. These estimates, however, are very dependent on the particular radical. The sensitivity achieved in practice also depends on the refinement of the apparatus. The typical values for various radicals using LMR, and in some cases EPR, spectrometers are listed in **Table 1**.

For applications in chemical kinetics, combined EPR/LMR spectrometers for both far- and mid-infrared regions have been developed. Three advantages are gained from this arrangement: (1) the versatility of the combined spectrometer, (2) the possibility of the absolute calibration of the LMR spectrometer by comparison of the LMR and EPR signals of the same radicals, and (3) usage of commercial EPR hardware for LMR detection. In the mid-infrared, EPR and LMR make use of a common detection zone. In the far-infrared, the detection zones of EPR and LMR are placed side by side; they cannot coincide, because of the large wavelength of the far-infrared laser.

Applications of LMR

Spectroscopy Studies

LMR has allowed the spectroscopic study of many free radicals that could not be detected by more conventional infrared techniques.

In **Table 2**, a list of the species detected by LMR upto 1998 is presented. For instance, detection of OH and OH_2 radicals in the lower stratosphere and upper troposphere has been achieved using LMR with a spectrometer mounted in an aircraft. However, the pace of developments has slowed, since many of the better-known free radicals accessible for LMR have now been observed. As for lesser-known free radicals, LMR is a difficult method for obtaining initial knowledge (at least for polyatomics) because the Zeeman effect must be

analysed as well as the zero-field spectrum. In the mid-infrared, the tunable semiconductor diode lasers are another factor in the development of infrared spectroscopy of high sensitivity and resolution, although LMR provides magnetic parameters inaccessible to the diode laser spectroscopy. In **Figure 3** the rise and fall of LMR are illustrated.

A typical spectroscopic study of a radical includes the following: recording of numerous LMR spectra, assignment of the observed resonances to quantum numbers, and determination of the parameters of the Hamiltonian (for both ground and vibrationally excited states in the case of vibrational-rotational spectra). Although the accuracy of these parameters (up to megahertz) is somewhat lower than that obtained by microwave spectroscopy, it is not restricted to rotational transitions but includes vibrational, fine structure, and hyperfine effects.

The main requirements for a successful LMR study are as follows: (1) paramagnetic atoms or molecules ($S > 0$ or $L > 0$); (2) the closeness of laser and transition frequencies ($< 1 \text{ cm}^{-1}$); (3) usually, no more than two heavy (not hydrogen) atoms (exceptions are non-hydride triatomics which are either linear (NCO , N_3 , and NCN) or have high-field LMR spectra due to level anticrossing mechanisms (FO_2 , ClSO , FSO , and ClO_2)); (4) a moderate transition dipole moment; and (5) detection of numerous resonances at numerous laser lines for successful extraction of the Hamiltonian parameters. If the spectra are complex and energy level predictions are not available, the data from other spectroscopic techniques are especially valid. Use of an LMR spectrometer based on a CO laser combined with the presences of Stark plates to generate an electric field has been used to measure the dipole moment of $^{15}\text{N}^{16}\text{O}$.

LMR in Chemical Kinetics

The combination of high sensitivity and versatility makes LMR attractive in chemical kinetics studies. Three experimental arrangements of LMR are usually employed.

- (i) The first are discharge-flow techniques in which the products of a microwave discharge and consequent chemical reactions are pumped rapidly through the detection zone of an LMR spectrometer. The

kinetics are obtained by varying the distance between the radical injector and the detection zone.

- (ii) The second is time-resolved LMR in which radicals are produced by either UV photolysis or multi-photon dissociation of a suitable precursor; the LMR signal kinetics is monitored.

These experimental arrangements for kinetics studies are not specific to LMR; they are widely used with other spectroscopic methods, such as EPR, LIF, mass spectrometry and so on.

- (iii) The third arrangement is specific to LMR; it is used to study only vibrational relaxation of radicals; an intracavity LMR spectrometer based on a CO₂ laser is usually employed. Radicals are prepared in a discharge-flow system; the kinetics of the LMR signal saturation by a CO₂ laser radiation field after a fast magnetic field jump are monitored. The magnetic field jump provides fast adjustment to the absorption spectral line of the radical. The saturation kinetics are exponential, the exponent decay time being

$$1/\tau = 2\sigma J_0 + \sum_i k_i [M_i]$$

where σ is the vibrational-rotational transition cross section, J_0 the photon flux density, $[M_i]$ the concentration of the i th gas relaxator, and k_i is the vibrational relaxation rate constant. This relation is used to obtain k_i by measuring τ at different $[M_i]$.

This method is applicable only to radicals that show sufficient saturation ($> 10\%$) of a vibrational transition

by the radiation field. The prerequisites for successful detection of the saturation are radiation intensity in the cavity of the CO₂ laser of $> 100 \text{ W cm}^{-2}$, a rather small rotational partition function ($\leq 10^3$, i.e., nonlinear radicals with low moments of inertia, or linear radicals), and moderate transition dipole moment ($\sim 0.1 \text{ D}$).

Symbols

E_{kin} initial kinetic energy of ions

Introduction

The defining attribute of laser microprobe mass spectrometry (LMMS) is the use of a focused laser to irradiate a 5–10 μm spot of a solid sample at a power density above 10^6 W cm^{-2} . The photon–solid interaction yields ions which are mass analysed by time-of-flight (TOF) or Fourier transform (FT) MS. The technique is sometimes referred to as laser probe microanalysis (LPA or LPMA), laser ionization mass analysis (LIMA) and laser microprobe mass analysis (LAMMA).

The use of lasers to ionize solids in mass spectrometry dates back to the early 1960s, when the first high-power pulsed lasers became available. These highly directional and intense monochromatic beams can be easily introduced in the confined space of ion sources without disturbing the electrical fields. Moreover, upon the photon interaction with nonconducting materials, no charging of the sample occurs. First, lasers became an interesting alternative for spark-source MS to quantify elements in dielectrical specimens. Later, the ultrafast heating of the solid by laser irradiation was exploited for the desorption and ionization (DI) of labile organic compounds without thermal decomposition. The growing interest in microanalysis triggered the application of a focused laser in the 1970s. The initial aim was again elemental analysis in nonconducting samples but the main strength of LMMS was found to be the molecule-specific information on the local constituents. Organic and inorganic compounds are characterized by a combination of fragments and adduct ions. The former arise from the structure-specific breakdown of the analyte. The latter simply consist of the intact analyte attached to one or more of these stable fragments.

The understanding of material properties on a local level implies knowledge of the chemistry and, hence, of the molecules present. Therefore the molecular specificity of LMMS is a major advantage in comparison with most micro- and surface analysis techniques, which characterize relative elemental abundances, bonds present or functional groups. Quantitation in LMMS is

difficult because adequate reference materials are not always available. However, qualitative identification of local constituents can often be achieved by deductive reasoning only. As a result, LMMS became appreciated as a versatile tool in diverse problem-solving applications in science and technology. The main sample requirement is its stability in the vacuum.

Instrumentation

The simple construction and operation, excellent transmission, and the registration of full mass spectra made a TOF analyser the obvious choice for the early LMMS instruments. Later it was found that the time definition of the ion production from the laser pulse was less suited to TOF MS than initially assumed. Also, the complex mass spectra required a significantly higher mass resolution and mass accuracy than that available in TOF LMMS. Hence, FT LMMS was developed. Although the laser microbeam ionization was retained, the species detected and their relative intensities differ significantly from TOF LMMS. The reason is that each MS may capture a different fraction of the initial ion population, depending on its acceptance with respect to the initial kinetic energy (E_{kin}), their time and place of formation in the ion source. Therefore, a clear distinction between TOF and FT LMMS is mandatory.

TOF LMMS

Figure 1 depicts a commercial instrument. The sample is mounted inside the vacuum chamber of the MS. The DI is commonly performed by 266 nm UV pulses from a frequency-quadrupled Nd:YAG (neodymium–yttrium–aluminium–garnet) laser. This instrument allows repositioning of the sample and the optics for analysis in transmission or in reflection. In the former case, the laser hits the lower surface of the sample while the upper surface faces the MS. This suits thin films or particles of about 1 μm on a polymer film. Reflection means that the beam impinges on the sample side facing the MS. The surface of bulk samples can thus be characterized. Micro-positioners allow one to move the spot of interest on the sample into the waist of the ionizing beam, which is visualized by a collinear He–Ne laser.

Figure 1 Schematic diagram of the LIMA 2A TOF LMMS. Reprinted from the LIMA technical documentation with permission of Kratos Analytical.

The UV-irradiated spot is typically 1–3 μm in TOF LMMS so that power densities between 10^6 and $10^{11} \text{ W cm}^{-2}$ can be attained with mJ pulses of 10–15 ns. Refractive objectives allow spot sizes down to the diffraction limit of 0.5 μm . Reflective optics (as in **Figure 1**) allow larger working distances and are free from chromatic aberrations so that use of other wavelengths is facilitated. Ionization with a tunable dye laser allows resonant one-step DI or postionization of the laser ablated neutrals. Specificity and sensitivity can thus be improved substantially but wavelength selection becomes cumbersome for unknown compounds.

The principles of a TOF mass analyser are covered in another article. Commercial TOF LMMS permits a mass resolution of about 500, a much lower value than theory predicts, and this figure strongly depends on the analyte. The reason is quite fundamental. The application of TOF implies that ions with different m/z and therefore different velocities must arrive at the same time at the entrance to the drift tube. The pulsed laser ionization does not meet this requirement as ion formation may continue long after the laser pulse, especially for organic compounds but also for inorganic analytes. As a result, mass resolution and mass accuracy may become problematic. The asset of an unlimited m/z range is cancelled by the low mass resolution. A major advantage is the inherent panoramic registration.

FT LMMS

Figure 2 illustrates an instrument with an external ion source and shows the different microprobe related

devices such as the optical interface, the micropositioners, the sample observation and the exchange system. This set-up features laser irradiation of the sample in reflection with a spot of 5 μm . Electrostatic fields transport ions through a differentially pumped transfer line from the source at 10^{-6} torr to the FT MS cell at 10^{-10} torr inside a 4.7 tesla magnetic field (B). Inherent advantages of FT MS are the routinely obtainable high mass resolution of over 100 000 at m/z 1000, and up to a few million below m/z 100, and the mass accuracy of better than 1 ppm up m/z 1000. Internal calibration of the m/z scale by adding a reference compound is not necessary as is the case in magnetic high-resolution mass spectrometers. A remarkable feature of FT MS is that better mass resolution means better sensitivity. This contrasts with other types of MS where resolution is increased by selecting a central fraction of the ion beam, thereby sacrificing sensitivity. The direct link of sensitivity and mass resolution in FT MS results from the influence of space charge effects, field imperfections and pressure in the cell. All these cause a faster decay of the coherence in the ion packets after excitation, which decreases mass resolution, but they also limit the quantitative trapping and/or the radius increase of the ion orbit during excitation, which diminish detection sensitivity. FT MS is also limited in the detection of low and high m/z by its detection bandwidth and B , respectively. A range between m/z 15 and 10 000 is common.

The use of FT MS in microanalysis implies that the technique is operated close to its detection limits. Therefore, the vacuum in the cell becomes a prime reason for external ion source be used for LMMS as

Figure 2 Schematic diagram of a FT LMMS with external ion source. Adapted from Struyf H, Van Roy W, Van Vaeck L, Van Grieken R, Gijbels R, and Caravatti P (1993) *Analytica Chimica Acta* 283: 139–151 with permission of Elsevier Science.

opposed to a single- or dual-cell instrument, where the sample is placed in the FT MS cell. Additionally, the E_{kin} of laser ions can exceed the energy range imposed by the optimal trapping potentials of typically less than 2 V. Biasing the sample holder or placing additional electrodes around the sample inside the cell disturbs the trapping field. Cooling of the ions by ion–molecule interactions is not always efficient. The use of micro-positioners, laser and observation optics inside the narrow bore of the strong magnetic field, is not obvious. However, injection of external ions requires temporary deactivation of the potential gradient in the hole of the first trapping plate. Upon reflection against the second trapping plate, ions come back and may escape unless the entrance is blocked. The use of an electrostatic transfer line causes a time dispersion of ions of different m/z as in TOF MS, i.e. the so-called TOF effect. To trap a high m/z ion together with a low m/z ion, the high m/z ion, which arrives later, must enter the cell before the low m/z ion (which arrived earlier and has been reflected by the second trapping plate) leaves the cell. In practice, the m/z ratio of high-to-low m/z ions that can be trapped simultaneously in the cell is about a factor of 3–4, depending on the time of ion formation and life time of the specific ions. Adapting the time between the laser pulse and the closure of the injection lenses allows one to shift the m/z window along the m/z range in successive experiments.

Analytical Characteristics

Table 1 surveys the common techniques for micro- and surface analysis of solids. Both static secondary ion mass

spectrometry (SSIMS) and LMMS provide molecular information on local organic and inorganic compounds. However, the primary interaction of keV ions with the sample in SSIMS as opposed to eV-range photons in LMMS makes the direct structural linkage of the detected signals to the sample composition less obvious in SSIMS. Hence, comparison with reference spectra is usually required in SSIMS, while LMMS allows a deductive interpretation. In fact, both methods are complementary with respect to their typical applications. SSIMS can detect high m/z ions from polymers, while LMMS yields more detailed structural information on analytes of up to a few kDa. SSIMS generates primarily ions from the upper monolayer, making surface contamination a problem in real-life applications. In contrast, ions in LMMS originate from the upper 10–50 nm surface layer, although the crater depth goes up to 0.1–1 μm . SSIMS allows imaging, while LMMS performs spot analysis.

The reproducibility of LMMS strongly depends on the positioning of the sample surface in the waist of the UV beam. Hence, mapping by motorizing the sample positioners is only feasible for extremely flat samples. As to the kind of materials analysed, LMMS requires stability in a vacuum of 10^{-6} torr but SSIMS needs a pressure of under 10^{-8} torr, which prevents the analysis of ‘volatile’ organic compounds. Charge build-up in dielectrical samples occurs in SSIMS, not in LMMS.

Quantification in MS requires adequate reference samples. For LMMS this means that not only the chemical composition but also the UV absorption, reflective and refractive properties of each microvolume must be comparable to ensure that the energy deposition and ion yield are similar. Hence, preparation of suitable

reference materials often becomes the bottleneck. Biological sections or ambient aerosols are chemically and optically heterogeneous, so that quantification is not feasible. On the other hand, element diffusion in the wafers from semiconductor applications can be quantitatively studied.

Diagnostic Use of the Mass Spectra

Model of Ion Formation

Deduction of the analyte composition from the signals requires that one must be able to extrapolate the mass spectra from a limited database and ideally predict the ions from a given analyte. Therefore, practical concepts about ion formation are mandatory. Figures 3–5, survey a tentative model for DI in LMMS, applicable to both organic and inorganic compounds. Basically, the ionization

Figure 3 Relationship between the energy regimes at the surface and the ion formation process according to the tentative model for DI in LMMS. Reprinted from Van Vaeck L, Struyf H, Van Roy W, and Adams F (1994) *Mass Spectrometry Reviews* 13: 189–208 with permission of John Wiley and Sons.

Figure 4 Effect of the local pressure on the type of ions formed according to the tentative model for DI in LMMS. Reprinted from Van Vaeck L, Struyf H, Van Roy W, and Adams F (1994) *Mass Spectrometry Reviews* 13: 189–208 with permission of John Wiley and Sons.

event is described in terms of the three prime parameters in MS, namely local energy, pressure and time.

First of all, laser impact is assumed to create different local energy regimes in physically distinct regions within and around the irradiated spot. Figure 3 depicts schematically the occurrence of atomization and destructive pyrolysis in hot spots, direct ejection of fragments and molecular aggregates from surrounding regions. Ultrafast thermal processes allow preservation of the molecular structure of even thermolabile analytes. The initial species will undergo fragmentation or subsequent ion–molecule interactions. Thermionic emission of e.g. alkali metal ions yields the necessary flux of ions to form adducts with the initially released neutrals and ion-pairs. This occurs primarily after the laser pulse in the selvage, i.e. the gas phase just above the sample.

Secondly, the local pressure must be considered. As shown in Figure 4, the released neutrals and ions give rise to a gradually expanding microcloud. Its initial density depends on the ‘volatility’ of the analyte, i.e. the number of species released at a given power density. The importance of ion–molecule interactions depends on the local pressure in this cloud, which determines the collision probability. In low-density regions, ions follow unimolecular behaviour and fragmentation only depends on the internal energy.

Finally, the timescale of the ionization is an essential feature of the approach since it must match the time window of detectable ions by a given mass analyser. The time evolution of the DI process is assumed to include two distinct phases. The schematic picture in Figure 5 shows that the ion-generation process comprises two consecutive contributions. An initial intense ion current is produced during the first 10–25 ns, compatible with detection in TOF LMMS. However, selvage ionization may already start in that initial period but will reach its maximum later and finally continues for microseconds after the end of the laser pulse. This process may be

Figure 5 Influence of the time domain of ion formation and of the analyser on the mass spectra recorded according to the tentative model for DI in LMMS. Reprinted from Van Vaeck L, Struyf H, Van Roy W, and Adams F (1994) *Mass Spectrometry Reviews* 13: 189–208 with permission of John Wiley and Sons.

small, but integrated over time; this contribution often prevails over the prompt DI. This rather slow DI component is not compatible with detection in TOF LMMS but is inherently included in the signal when magnetic mass spectrometers or FT MS ion traps are used.

This tentative DI model does not give an accurate description of all the physical processes involved, but up to now, it allows a consistent explanation of the formation of the ions detected. Also, it unifies the processes of organic and inorganic ion formation and allows rationalization of the differences between TOF and FT LMMS spectra as to the species detected and their relative intensities. Moreover, it allows linkage of LMMS to the older literature on the soft ionization of organic compounds by defocused lasers and magnetic analysers, where fragmentation was virtually absent.

Inorganic Speciation

Figure 6 illustrates how FT LMMS signals can be used for analyte identification. The low m/z fragments and their adducts to the original molecule readily allow tentative identification of an unknown compound by deductive reasoning alone. This represents a major advantage in e.g. industrial materials-science applications, where many not well-characterized reagents are possible causes of anomalous behaviour. Recording reference spectra of all possible candidates for the given anomaly

could be time consuming if one cannot select deductively the most likely one.

The most demanding speciation task is the distinction between analytes with the same elements but in different ratios, e.g. sodium sulfate, sulfite and thiosulfate. The positive fragments Na^+ , Na_2O , $\text{Na}_2\text{O} \cdot \text{H}^+$ and $\text{Na}_2\text{O} \cdot \text{Na}^+$ as well as the signals from $\text{Na}_2\text{SO}_3 \cdot \text{Na}^+$ and $\text{Na}_2\text{SO}_4 \cdot \text{Na}^+$ are observed by FT LMMS for all three analogues. However, only thiosulfate produces additional peaks for cationized Na_2S , which characterize the presence of the sodium-sulfur bond in this analogue. Adduct ions of $\text{Na}_2\text{S}_2\text{O}_3$ are also seen at low intensity. Distinction can be based on the ratio of the ions $\text{Na}_2\text{SO}_3 \cdot \text{Na}^+$ to $\text{Na}_2\text{SO}_4 \cdot \text{Na}^+$, which is 0.82 ± 0.13 for sulfite and 0.30 ± 0.06 for sulfate. The production of cationized sulfate from sulfite and vice versa is rationalized by the relatively high-energy regime in the hot spots, where the stability of the formed ion prevails. Nevertheless, the softer regime of the periphery is assumed to produce the cationized analyte and thereby restores the logical connection with the original composition. The major signals in the negative mode are found at the nominal m/z values of 64 and 80 and are common for all three analogues. However, these signals are uniquely due to SO_2^- and SO_3^- for sulfite and sulfate, while thiosulfate produces additional contributions from S_2^- and S_2O^- also at m/z 64 and 80 respectively. The FT LMMS high mass resolution is needed to exploit such distinctive features.

Figure 6 Scheme for the deductive identification of the analyte molecular composition from mass spectra taken by FT LMMS. Reprinted from Struyf H, Van Vaeck L, Poels K, and Van Grieken R (1998) *Journal of the American Society for Mass Spectrometry* 9: 482–497 with permission of Elsevier Science.

Identification of Organic Compounds

Deductive identification is even more important in organic microanalysis because of the numerous structures for each molecular weight. **Figure 7** shows the positive and negative TOF LMMS data of a microscopic residue, obtained from the eluate of a single peak from analytical HPLC. The nanogram amount of available material was not consumed significantly after microprobe analysis although it was insufficient for conventional MS. The latter required the combination of fractions from numerous elutions to yield

the mass spectrum of miconazole, the parent drug. In contrast, TOF LMMS detected the protonated molecules by the cluster of isotope peaks around m/z 503. Subsequent loss of HCOOH yields the fragments around m/z 457, while the accompanying lower m/z signals are readily rationalized by the known ring formation and rearrangement mechanisms in organic MS. Complementary information comes with the negative ions. Specifically the fragment at m/z 153 serves to specify further the presence of the imidazole methacrylate function in the molecule. This example highlights two features of the LMMS technique,

Figure 7 Positive and negative mass spectrum recorded by TOF LMMS from the residue of the eluate of a single peak in analytical HPLC. Reprinted from Van Vaeck L and Lauwers W (1989) *Advances in Mass Spectrometry* 11a: 348–349 with permission of Heyden and Son.

namely the minute material consumption and the deductive identification of labile compounds without thermal destruction as a result of the ultrafast heating rate of the solid.

Comparison of Mass Spectra Recorded by TOF LMMS and FT LMMS

Several characteristic differences are observed between the mass spectra, recorded by FT LMMS and TOF LMMS from the same analyte under the same experimental conditions with respect to laser wavelength, pulse duration and power density. While FT LMMS offers superior mass resolution and mass accuracy in comparison to TOF LMMS, the TOF effect in FT LMMS with an external source (see earlier sections on TOF LMMS and FT LMMS) means that only partial mass spectra in given m/z windows can be recorded (TOF LMMS always yields mass spectra that cover the entire m/z range). As well as these directly instrument-related differences between FT LMMS and TOF LMMS, the mass spectral patterns still reflect additional distinctive features. Specifically, more intense signals from the adduct ions in comparison to the summed intensities of the fragments are seen in FT LMMS as compared to TOF LMMS. This is related to the increased sampling of the selvedge contribution to the initial ion population, created by the laser impact. Also the existence of the two contributions, i.e. direct ion emission from the solid and the selvedge recombination in the gas phase, could be observed by selectively tuning the ion source in FT LMMS so that only one of the contributions had initial energies within the 1 eV trapping energy of the cell. Note that this increased adduct ion detection in FT LMMS applies to both organic and inorganic compounds. For instance, cation and anion adducts of molecules and even dimers are generally detected in FT LMMS from virtually all salts such as Na_2SO_4 , Na_3PO_4 , oxides and binary salts, as opposed to TOF LMMS. Additionally, FT LMMS shows increased signal intensities specifically for fragment ions associated with the fragmentation of adduct ions with low internal energy. Such ions are observed to undergo the loss of small neutral molecules, while ions with high internal energy are subject to more drastic cleavages and rearrangement, which may reduce structural specificity. Finally, TOF LMMS is often handicapped in the analysis of high molecular mass and polar substances. These compounds are hard to desorb from the solid without the aid of matrix-assisted techniques, which require dissolution of the sample in a UV-absorbing matrix and, therefore, are incompatible with the direct local analysis of as-received solid samples. Especially for such strongly adsorbed compounds, the slow release of the analyte over a long time interval (up to several microseconds) occurs (continuing postlaser

desorption). The adducts formed upon recombination with for instance Na^+ (also thermionically emitted for long periods after the laser pulse) no longer fulfil the TOF LMMS requirement of ion formation within 25 ns. As a result, these ions give rise to broad unresolved peaks or even to a continuous background. However, in FT LMMS, ions formed within a period of 50 μs to several hundreds of μs (depending on the m/z) after the laser pulse are still trapped in the FT LMMS cell together with the ions formed during the laser pulse. As a result, the range of compounds to which FT LMMS can be applied significantly extends towards higher molecular mass and polarity as compared to TOF LMMS.

Selected Applications

Review of the literature reveals that LMMS is applied to a wide variety of problems in the field of bioscience, environmental chemistry and materials research. Complete coverage is not feasible in this contribution, which only aims to demonstrate the strengths of the method. Specifically, LMMS excels at yielding, within a relatively short period, qualitative information on the organic or inorganic local surface components from the most diverse samples, often with negligible sample preparation.

The transmission type TOF LMMS instruments especially suits biomedical section samples as commonly used for optical and electron microscopy. The lateral resolution of 0.5 μm allows experiments at the subcellular level. Initial work has concentrated on the localization of elements in specific sites of the tissue. Typical examples involve the assessment of aluminium levels in the bones of chronic haemodialysis patients, the study of lead accumulation in kidneys and calcifications in intraperitoneal soft tissue as a result of chronic lead intoxication, and the detection of several heavy metals in the amalgam tattoos of the oral mucosal membrane and human gingiva in direct contact with dental alloys. The relatively low lateral resolution, the lack of automated mapping and the almost impossible quantization strongly hinder the use of LMMS, especially in view of analytical electron microscopy (AEM) with X-ray analysis and the emerging possibilities of nuclear microscopy.

As a result, experiments have become gradually directed towards applications where the direct extraction of molecular information from the biological sector could be exploited. Interpretation of the mass spectra in TOF LMMS with low mass resolution may become problematic when the local microvolume comprises a complex multi-component system. As a result, applications were especially successful when LMMS was used to characterize the micrometre-size microliths and foreign bodies, often found in histological sections. In this way, the spheroliths in the Bowman's membrane of patients suffering from primary

Figure 9 FT LMMS analysis of an additive coating on aluminium. Reprinted from Poels K, Van Vaeck L, Van Espen P, Terryn H, and Adams F (1996) *Rapid Communications in Mass Spectrometry* 10: 1351–1360 with permission of John Wiley and Sons.

atypical bandkeratopathy and the intrarenal microliths, formed after the administration of high doses of cyclosporin were proven to consist of hydroxyapatite. Implants often lead to long-term problems by dispersion of wear particles in tissues, leaching of specific compounds and sometimes subsequent chemical transformation. The pathogenesis of the aseptic loosening of joint prostheses was related to the presence of zirconium oxide in the granular foreign bodies of surrounding tissue. This compound was added to the bone cement to enhance the contrast in later X-ray radiographs.

Examples of characterization of organic molecules include the detection of deposits from an anti-leprosy drug in the spleen of treated mice. The study of biomedical sections is not the exclusive field of TOF LMMS, although the lower lateral resolution of FT LMMS limits the number of applications. However, the much better specificity from the superior mass resolution and mass accuracy pays off with increasing complexity of the local composition. FT LMMS is particularly appreciated because of the separation of isobaric ions in the tissue, such as CaO^+ and Fe^+ ions, the facile assignment of a signal as an 'organic' ion or an 'inorganic' cluster on the basis of accurate m/z values, and the increased contribution of ions from the selvedge, which decreases the influence of the local laser power density on the mass spectra. Practical applications widen the range, initiated by TOF LMMS. For instance, the foreign bodies in the inflamed tissue around implants were identified as wear particles from a titanium knee-implant. Other experiments involved the verification of the local molecular composition deduced from relative element abundances in AEM. The apoptotic cell death in the tissue around vein grafts was associated with the presence of hydroxyapatite because of the intense Ca and P signals in AEM. FT LMMS clearly showed the erroneous nature of this conclusion since both elements did not belong to the same molecule. This clearly illustrates the importance of molecular information in microanalysis.

Figure 8 illustrates the application of FT LMMS for the *in situ* identification of pigments in a lichen, *Haematomma ventosum*. The interest in such natural products relates to the understanding of their role in the interception of sunlight and their possible interaction in energy transfer. The optical micrograph shows the dark-red dish-like fruiting bodies or apothecia on the light coloured thallus. The combination of positive and negative ion mass spectra taken from the apothecia gives quite a detailed picture of the molecule. Specifically, the molecular mass is available from the potassium adduct and the numerous fragments serve to deduce structural features. The material is analysed as it is found in nature, without any prior sample preparation.

As to materials research, diverse problem-solving examples of LMMS are described. Typical examples

involve the identification of local heterogeneities in poorly dispersed rubbers as one of the ingredients of the formulation, the tracing of the origin of occasional organic and inorganic contaminants at the surface of microelectronic devices and the study of segregation and formation of specific compounds in the joints of welded or heat-treated oxide-dispersion-strengthened alloys. Particularly interesting is the study of the dispersion of the magnetic elements inside the polyethylene terephthalate matrix at the surface of faulty computer discs. Here the capability to detect both inorganic ions and organic structural fragments in the same spectrum is essential for trouble shooting.

A final example illustrates how LMMS can contribute to the fundamental understanding of processing of materials. Specifically, aluminium strips and plates are produced by hot rolling the primary alloy ingots under high pressure and temperature. The lubricating emulsions contain numerous additives, whose composition is empirically optimized. Sometimes, given constituents adhere or interact with the surface and cause optical defects upon subsequent coating or surface treatment. FT LMMS was used to study the possible additive-metal interactions. The data in **Figure 9** for triethanolamine (TEA) oleate on aluminium show the normally expected simple adduct and fragments, as well as particularly interesting signals due to ions, which include multiply charged anions with Al^{3+} . Since only singly charged aluminium is formed in laser microbeam DI, these Al^{3+} -containing ions must exist as such in the solid and undergo direct ejection. This implies that TEA oleate is likely to bind effectively to the metal, while this additive is often considered as a chemically nonaggressive surfactant in the lubricating emulsions.

To conclude, it should be mentioned that one of the major breakthroughs in the field of organic MS emerged from the research on the initial TOF LMMS instruments. Indeed, the now booming field of matrix assisted laser desorption ionization (MALDI) for the characterization of high molecular mass compounds up to 230 kDa found its roots in the laboratory of Prof. Hillenkamp, which was one of the driving forces behind the development of the initial TOF LMMS instruments. It shows the ingenuity of chemists in exploiting the powerful combination of laser ionization and MS. As to local analysis, the second generation of LMMS, FT LMMS, seems to represent a major step in the search for a versatile microprobe, enabling us to characterize the molecular composition of organic and inorganic compounds at the surface of almost any type of solid, electrically conducting or not, with minimal sample preparation.

Symbols

A	amplitude of a plane polarized laser beam
c	speed of light
C	ground state concentration
E	electric field
E_r	energy of level <i>r</i>
g⁽ⁿ⁾	degree of <i>n</i> th order coherence
I	beam irradiance
J	irradiance level producing ionization or dissociation
l_c	coherence length
M	mean number of photons
M_{fi}	quantum probability amplitude
Q	quality factor
r	radial displacement from the beam centre
t	time
T⁽ⁿ⁾	molecular response tensor
V(ξ)	interaction operator for species ξ
V	volume
w	beam radius
w₀	focused beam radius
W	instantaneous beam power
α	absorption coefficient
ε₀	vacuum permittivity
Γ	transition rate
θ	angle of convergence of the focused beam
μ^{fi}	transition dipole moment
λ	wavelength
μ(ξ)	electric dipole operator of species ξ
E(ξ)	electric field vector at the position occupied by species ξ
ρ_f	number of energy levels per unit energy interval
ν	frequency
ω	circular frequency
ħ	Planck's constant/2π

The theory underlying electronic spectroscopy with lasers is essentially the theory of visible or ultraviolet photon interactions. Any spectroscopic technique based on laser instrumentation might in principle be studied with some other kind of light source, but usually at the expense of data quality in terms of signal-to-noise or resolution. The distinctive features that arise with the

deployment of laser light in electronic spectroscopy are principally those that relate to or exploit the qualities of the electric field produced by the laser beam. The customarily high level of monochromaticity affords the means to obtain high-resolution data, and high field strengths offer scope for the study of multiphoton processes. Another widely vaunted attribute of the laser, the coherence of its output, is only indirectly relevant to spectroscopic applications. In the so-called ‘coherence spectroscopies’ such as self-induced transparency and photon echo, laser coherence is significant only in enabling short and highly intense pulses to be created.

Electric Field and Intensity

Laser electronic spectroscopy is primarily based on coupling between the electron clouds of individual ions, atoms, chromophores or molecules of the sample with the electric field of the impinging laser radiation. The coupling is usually of dipolar character, and its detailed involvement in photonic interactions is to be discussed below. First, it is expedient to characterize the electric field, and to relate it to the laser intensity – as the latter is more directly amenable to experimental measurement. The electric field produced by a coherent, parallel, radially symmetric and plane polarized laser beam propagating in the *z*-direction, with a wavelength λ and a frequency ν , oscillates sinusoidally in time and space and has an amplitude A which depends on the radial displacement r from the beam centre:

$$E(z, r, t) = A(r)\cos(kz - \omega t + \phi) \quad [1]$$

Here $k = 2\pi/\lambda$, the ‘circular frequency’ $\omega = 2\pi\nu$ and ϕ is the phase. The vector character of the electric field is in general determined by the state of polarization, as discussed later: in the case of plane polarization it is directed along a unit vector $\hat{i}$ perpendicular to the *z*-direction of propagation. In cases where the line width of the radiation is significant the amplitude additionally has a frequency dependence and, particularly in the case of pulsed radiation, it also varies with the time t .

The beam irradiance I (the power per element of cross-sectional area), to which the electric and magnetic fields of the radiation contribute equally, is in general given by

$$I(r, \nu, t) = \frac{1}{2}c\epsilon_0 A^2(r, \nu, t) \quad [2]$$

The beam thus has radial, frequency and temporal intensity profiles. The radial profile is determined by the mode structure, reflecting the pattern of standing waves sustained within the laser cavity. In the simplest or ideal uniphase case, radiation tracks back and forth in an exactly axial fashion between the end-mirrors. With no hard edge, the beam is then described by an essentially Gaussian distribution, with a beam diameter $2w$ defined as the transverse distance between points at which the irradiance drops to $1/e^2$ (13.5%) of its central value, $I(0)$:

$$I(r) = I(0)\exp[-2(r/w)^2] \quad [3]$$

Accordingly, the electric field amplitude falls away as $\exp[-(r/w)^2]$. For a beam of instantaneous power W , the beam centre irradiance $I(0)$ is given by

$$I(0) = 2W/\pi w^2 \quad [4]$$

Fundamental considerations show that any laser beam can only be focused down to a limiting width whose diameter is of the same order as the wavelength – this is the diffraction limit. The focused beam diameter $2w_0$ is generally determined by the relation

$$w_0 = 2M^2\lambda/\pi\theta \quad [5]$$

where λ is the wavelength and θ the angle of convergence of the focused beam. The quantity M^2 is a measure of beam quality and has a diffraction-limited value of unity for a fundamental Gaussian-mode beam as represented by eqn [3].

The frequency profile of the laser beam is usually characterized by its full-width at half-maximum (FWHM), $\Delta\nu$. The single parameter that most effectively characterizes the degree of monochromaticity is then the quality factor Q , defined as the ratio of the laser emission frequency to its line width. It is also expressible as the coherence length l_c (the distance over which photons remain effectively in phase) divided by the wavelength:

$$Q = \nu/\Delta\nu = l_c/\lambda \quad [6]$$

In absorption-based laser spectroscopy this parameter represents an upper limit on the achievable resolution, which in practice may be reduced by other features of the instrumentation.

The issue of temporal profile is one that primarily relates to pulsed lasers, whose high powers result from their delivery of energy over a short period of time rather than continuously. For such devices the detailed temporal profile of the intensity $I(t)$ is determined by the means of pulsed operation. Individual pulses from giant pulse lasers seldom have the smoothly symmetric shape needed to follow any simple analytic form – and although the more

closely symmetric pulses from a mode-locked train are often characterized as having Gaussian shape, that more than anything reflects their characterization by averaging over a large number of pulses. The sech^2 intensity profile widely regarded as ideal is, however, achieved in pulses from many of the newer generation of ultrafast lasers.

Even continuous-wave laser light generally exhibits temporal fluctuations as a result of imperfect coherence, and the probability of finding a single photon in the volume of space V occupied by the species of spectroscopic interest generally approximates to a Poisson distribution. With a mean number of photons M given by

$$M = \frac{IV\lambda}{hc^2} \quad [7]$$

the probability P_N of finding N photons is

$$P_N = \frac{M^N e^{-M}}{N!} \quad [8]$$

Interaction of Light and Matter

In formulating the general theory it is helpful first to establish the dipolar response of each ion, atom, chromophore or molecule ξ to the oscillating electric field of the radiation. This is associated with an interaction operator:

$$V(\xi) = -\mu(\xi) \cdot E(\xi) \quad [9]$$

where $\mu(\xi)$ is the appropriate electric dipole operator and $E(\xi)$ the electric field vector at the position in space occupied by the species ξ . Electric dipole coupling accounts for the vast majority of the observations in electronic spectroscopy, though other kinds of multipolar interaction (such as electric quadrupole or magnetic dipole) can permit otherwise ‘forbidden’ transitions to occur, through a coupling which is typically weaker by a factor of 10^2 or 10^3 .

Even with the high laser intensities employed for the study of multiphoton processes, the electric fields they produce are seldom comparable to intramolecular coulombic fields. As such, the interaction operator [9] can be treated as a perturbation on the molecular states. The result of these perturbations is to modify the form of the Schrödinger equation so that its usual eigenfunctions no longer represent stationary states, and hence transitions occur. The quantum amplitude for a transition between a given initial state i and a final state f is given by the following result from time-dependent perturbation theory, expressed in Dirac notation:

$$M_{fi}(t, t_0) = \langle f | U_I(t, t_0) | i \rangle = \left(\frac{1}{i\hbar} \right)^n \langle f | \int_{t_0}^t dt_1 \times \int_{t_0}^{t_1} dt_2 \dots \int_{t_0}^{t_{n-1}} dt_n \tilde{V}(t_n) | i \rangle \quad [10]$$

where

$$\tilde{V}(t_i) = \exp\left(\frac{iH_0(t_i - t_0)}{\hbar}\right) V \exp\left(-\frac{iH_0(t_i - t_0)}{\hbar}\right) \quad [11]$$

and H_0 is the normal, unperturbed, Schrödinger operator for the molecule. Except for measurements with the most extreme time resolution, evaluation of the quantum amplitude given in eqn [10] leads to an essentially time-independent result and yields a corresponding transition rate Γ given by Fermi's 'Golden Rule':

$$\Gamma = \frac{2\pi}{\hbar} |M_{fi}|^2 \rho_f \quad [12]$$

Here ρ_f is the number of energy levels per unit energy interval, the so-called 'density of states'. Though often overlooked, the size of this latter factor contributes significantly to the ultrafast rates of transitions observed to occur in many large molecules, as a result of their tightly packed quasi-continua of vibronic levels. With increasing n , successive orders of the perturbation series [10] represent a progressively diminishing coupling, with a scale corresponding to the ratio of the radiative electric field in relation to intramolecular coulombic fields. Together, eqns [1], [2] and [9]–[12] correspondingly show that each additional photon interaction typically reduces the rate by a factor of the order (I/J) , where J is a level of irradiance which would produce ionization or dissociation – its value is generally in the region $10^{18 \pm 4} \text{ W m}^{-2}$. This figure is substantially undershot in most laser excitation experiments, and as a result the higher orders of photon interaction demand increasingly sensitive detection.

Single-Photon Absorption

For a process of single-photon absorption, the quantum amplitude is simply given by

$$M_{fi} = -\mu^{fi} \cdot E \quad [13]$$

using the convenient shorthand for the vector transition dipole moment, $\mu^{fi} = \langle f | \mu | i \rangle$. The rate Γ as given by eqn [12] depends quadratically on the electric field, and hence through eqns [1] and [2] exhibits a linear dependence on the laser intensity.

It follows that, since absorption produces a diminution of the laser intensity on passage through the absorbing sample, the rate of intensity loss is proportional to its instantaneous value, $-dI(t)/dt \propto I(t)$. In the case of pulsed irradiation, if the amount of absorption per pulse is small and decay processes from the excited state occur on a timescale that is slow compared with the pulse duration, the net absorption per pulse is proportional to the pulse energy. More generally, as the distance z the radiation travels through the sample is proportional to time t through the speed of light, we also have

$-dI(z)/dz \propto I(z)$. Thus the amount of absorption depends on the path length through Beer's law:

$$I(z) = I(0) \exp(-\alpha C z) \quad [14]$$

where α is the absorption coefficient and C the concentration of (ground state) absorbing species. The former is calculable from secondary effects pursuant on the absorption, or more directly from the relative attenuation of the excitation beam. Weak absorption leads to an intensity loss which has an almost directly linear dependence on distance, as follows from Taylor series expansion of the right-hand side of eqn [14].

Laser excitation here offers few distinctive features at the molecular level, except that at high levels of intensity the increased flux can lead to saturation. Then, a significantly high proportion of the sample molecules undergoes transition to an excited state and, as C varies through depletion of the ground state population, departures from Beer's law arise. This is a phenomenon that is exploited for analytical purposes with pulsed radiation, in concentration-modulated absorption spectroscopy.

The selection rules associated with single-photon absorption stem from its dependence on the transition dipole moment, which must be non-zero for absorption to occur. To satisfy this fundamental requirement, the direct product symmetry species of the initial and final wavefunctions must contain the symmetry species of the dipole operator – the latter transforming like the translation vectors x , y and z . Probably the most familiar aspect is the Laporte selection rule for centrosymmetric molecules, which allows transitions only between states of opposite parity, gerade (g) $\leftrightarrow$ ungerade (u).

For single-photon absorption in isotropic media, there is essentially no dependence on beam polarization. Such dependence as does exist arises only for optically active (chiral) compounds, and is associated with quantum interference between electric dipole and magnetic dipole (or electric quadrupole) interactions. These weak effects produce the characteristic polarization dependence that is manifest in the phenomena of circular dichroism and optical rotation.

Multiphoton Absorption

For processes involving the absorption of n photons from a single laser beam, energy conservation dictates

$$n h \nu = E_f - E_i \quad [15]$$

Multiphoton absorption of this kind is essentially a concerted rather than a multistep process, as there is no physically identifiable intermediate stage between the absorption of successive photons. It is, therefore, necessary for the absorbing molecule to be intercepted by the

necessary number of photons almost simultaneously, a condition which can seldom be satisfied other than by the use of pulsed laser radiation.

Determination of the rate of n -photon absorption from the Fermi rule [12] invokes the quantum amplitude for the process as given by eqns [9]–[11]. In the case of two-photon absorption, for example, we obtain a quadratic coupling with the impinging electric field:

$$M_{fi} = -S_{\alpha\beta}^{fi}(\omega) : E_{\alpha}E_{\beta} \quad [16]$$

a tensor counterpart to the scalar product of the single-photon result shown in eqn [13], in which α and β here represent the Cartesian indices x, y and z . Equation [16] is written in this concise form (with obvious extension to higher orders) through adoption of the Einstein convention for summation over repeated tensor indices, that is both α and β in the above expression are implicitly summed over x, y and z . The molecular response exhibited in eqn [16] is cast in terms of a two-photon tensor whose explicit structure is as follows

$$S_{\alpha\beta}^{fi}(\omega) = \sum_r \left[\frac{\langle f | \mu_{\alpha} | r \rangle \langle r | \mu_{\beta} | i \rangle}{E_r - E_i - \hbar\omega - i\Gamma_r} \right] \quad [17]$$

in which there is summation over a set of contributions from each molecular state r , of energy E_r and FWHM Lorentzian line width $2\Gamma_r$. Again the extension to higher orders follows, each additional photon interaction introducing one further transition dipole in the numerator and also an additional energy denominator term. For all but the simplest cases the exact form of these is best determined through quantum electrodynamical methods using Feynman time-ordered diagrams.

In general the n -photon quantum amplitude exhibits an n th power dependence on the electric field and accordingly the rate given by eqn [12] depends on the n th power of the laser irradiance I . The lack of coherence which is manifest as intensity fluctuations in the beam generally means that the time-average value of I^n differs from $\bar{I}^n$, where $\bar{I}$ is the mean irradiance. Consequently the result is usually cast instead in terms of $g^{(n)}\bar{I}^n$, where $g^{(n)}$ is the degree of n th order coherence – having the value of unity for a perfect Poissonian source.

In the case of pulsed radiation the extent of absorption depends on the integral $\int I^n(t)dt$ and so involves not only the energy of the pulse but also the temporal profile of the latter. Equally, the radial profile of the beam has a bearing on the extent of absorption. In particular, the nonlinear dependence on intensity means that if the laser beam is focused within a medium exhibiting multiphoton absorption, most of the absorption occurs at the focus. For example, a Gaussian beam focused from a beam waist w to the diffraction-limited value w_0 as given by eqn [5] generates across its focus a net absorption which is

$(w/w_0)^{2n}$ times larger than across the unfocused beam. This principle is exploited in imaging techniques based on the detection of fluorescence resulting from multiphoton absorption.

Through the nonlinear intensity dependence, Beer's law condition totally fails to be satisfied in processes involving the absorption of two or more photons, and results cannot be given in terms of conventional absorption coefficients. Again, for two-photon absorption the counterpart to eqn [14] takes the form

$$I(z) = I(0)/(1 + \beta Cz) \quad [18]$$

where β determines the strength of the two-photon transition. However, the weakness of the absorption generally means that the leading terms of a Taylor series for the right-hand side of eqn [18] provide a very good approximation for the beam attenuation $\Delta I = I(0) - I(z)$, which then displays the same essentially linear dependence on distance as weak single-photon absorption.

It is evident from the form of eqn [17] that the two-photon tensor, and hence the extent of two-photon absorption, is significantly enhanced if the molecule possesses an electronic excited state of an energy close to $E_i + \hbar\omega$, for then, in the sum over r , the term that state contributes has an absolute minimum value for the denominator. This situation, typical of multiphoton processes, is known as resonance enhancement, and its physical basis can be understood in terms of the time-energy uncertainty principle:

$$\Delta E \Delta t \geq \frac{1}{4} \hbar \quad [19]$$

In frequency regions well removed from resonance, absorption of the first laser photon leads the molecule into a state with a large ΔE , that is one that is energy non-conserving. Accordingly, the molecule can exist in such a state only if further absorption restores energy conservation within a correspondingly short time. However, if the first photon is near resonance with a real molecular state, the intermediate state has a small ΔE and can persist for much longer. This greatly increases the probability that the next photon will arrive within the necessary window. In the limit where exact resonance occurs and ΔE is zero, there is no longer any temporal constraint save for the decay lifetime of the resonant state, as that state can be physically populated by single-photon absorption. Then the two-photon process can be completed in a second stage, without the need to fulfil the exacting conditions for both photons to arrive at the same instant. Under resonance conditions the power law for the intensity dependence is also in general modified to reflect the greater significance of whichever stage is the rate-determining step.

Each photon interaction in a multiphoton process governed by dipole coupling is subject to the Laporte selection rules. However, the product selection rules depart substantially from the normal results; for example, if an even number of photons are involved, as in Raman scattering, two-photon absorption and four-wave mixing, then the selection rules $g \leftrightarrow g$ and $u \leftrightarrow u$ apply. In general, for a given transition to occur it is necessary that the molecular response tensor possesses at least some non-zero elements. The criterion for this rule to be satisfied is that the product of the irreducible representations of the molecular initial and final states must be spanned by one or more components of the tensor. The representation of the (electric dipole) molecular response tensor $T^{(n)}$, for a process of n -photon absorption from a single beam, has the following general decomposition into irreducible parts or weights $n, (n-2) \dots$

$$\mathcal{D}(T^{(n)}) = \mathcal{D}^{(n\varphi)} \oplus \mathcal{D}^{((n-2)\varphi)} \oplus \dots \quad [20]$$

where for even n the parity $\varphi = +1$ and for odd $\varphi = -1$, and the series terminates with $\mathcal{D}^{(0\varphi)}$ or $\mathcal{D}^{(1\varphi)}$ respectively. For molecules of reasonably high symmetry, the operation of the multiphoton selection rule leads to far more states being accessible through multiphoton processes than through conventional single-photon absorption.

Polarization Effects

Laser beam polarization plays an obvious role in the orientational effects displayed in photoabsorption by anisotropic media such as crystals, liquid crystals and surfaces. However, strong pumping with a plane polarized laser beam can induce anisotropy in an originally isotropic sample. This results from the fact that the probability of single photon depends on $\cos^2\theta$, where θ is the angle between the relevant molecular transition moments and the photon electric field vector, as in eqn [13]. High intensity pulsed laser radiation can thus create a preferentially oriented population of excited molecules, a process termed photoselection. In many cases rotational relaxation nonetheless destroys this anisotropy within a matter of picoseconds after the inducing laser pulse.

The electric field of laser light need not oscillate in a single plane, and often optics are employed to produce other polarizations with a degree of circularity. Circular

polarizations are important in forms of laser spectroscopy which exploit angular momentum selection rules, because the photons carry unit quanta of angular momentum. With chiral substances, a small degree of sensitivity to the handedness of the radiation is also manifest in the circular differential response. For two-photon and higher-order processes, however, even the spectra of reasonably symmetrical molecules display a marked dependence on polarization.

For generality the polarization state of the laser beam can be expressed in a form that can accommodate arbitrary plane, circular or elliptical states. Instead of the i which determines the direction of the electric field in eqn [1], we then have a unit polarization vector given by

$$\mathbf{e} = e^{i\phi} \cos \sigma \hat{X} + e^{i\zeta} \sin \sigma \hat{Y} \quad [21]$$

where

$$(\sigma, \phi, \zeta) \mapsto \begin{cases} (\pi/4, 0, \pi/2) & \text{R-circular polarization} \\ (\pi/4, 0, -\pi/2) & \text{L-circular polarization} \\ (\pi/2, 0, 0) & \text{p-polarization} \\ (0, 0, 0) & \text{s-polarization} \end{cases} \quad [22]$$

where the latter mutually orthogonal plane polarizations are given the labels that would usually be employed in connection with irradiation of a surface with normal vector Z .

Introduction

Screening using NMR cannot match in speed and limit of detection screening by high-throughput screening (HTS), but the information content from protein–ligand binding and screening experiments by NMR can be greater, and much weaker binding can be detected. Therein lies the advantage of screening a generally smaller and more tightly focused library of compounds by NMR techniques as compared to HTS screens.

There are two general types of experiments for detection and measurement of ligand–protein binding: ligand detected and target detected. In ligand-detected experiments the ligand resonances are observed and conclusions are drawn based on the effect binding to the target or protein has on the ligand resonances. Target-detected experiments instead rely on detecting the position of protein resonances in the presence and absence of ligand. The choice of target-detected or ligand-detected screening techniques depends on the information that the experiments must produce and specifics of the system under investigation.

Exchange

In protein–ligand binding experiments, exchange refers to the ligand exchanging between a free state, [L], and the bound state (bound to the protein), [LP], according to the equilibrium shown in eqn [1]:

The binding affinity can be described by the dissociation constant K_D , which is equal to the ratio of the off (dissociation) and on (association) rate constants (k_{off} and k_{on} , respectively), for the equilibrium in eqn [1]:

$$K_D = \frac{[L][P]}{[LP]} = \frac{k_{\text{off}}}{k_{\text{on}}} \quad [2]$$

Since $1/k_{\text{off}}$ is the lifetime of the LP complex, this value is related to the exchange timescale. For example, if k_{off} is greater than the difference between the free and bound ligand resonance chemical shifts, the exchange is fast on the chemical shift timescale. When exchange is fast on the timescale of the effect being observed (e.g., chemical shift, relaxation, and diffusion coefficient), the observed effect on the ligand resonances will be a population-weighted average of the effect the ligand experiences in the two states.

By substituting the expression for fraction of enzyme bound ($F_b^E = [LP]/[LP] + [P]$) into eqn [2], an expression for the fraction of enzyme bound in terms of only ligand concentration and K_D can be derived as shown in eqn [3]:

$$F_b^E = \frac{[L]}{[L] + K_D} \quad [3]$$

According to eqn [3], when $[L] \gg K_D$ and $[L] > [P]$, F_b^E will approach 1.0 and the protein-binding site will become saturated with ligand. Also, when $[L] = K_D$, half of the protein-binding sites will be occupied ($F_b^E = 0.5$, assuming a 1:1 complex is formed). Expressing the fraction of bound enzyme as a function of K_D and ligand concentration also emphasizes that the ligand concentration can be used to tune the K_D range that the experiment can be used to detect. Limiting the ligand concentration can be used as a way of avoiding the detection of excessive nonspecific binding, which is usually weaker than specific binding, or limit the detection of very weakly binding ligands.

Ligand-Detected Experiments

Ligand-detected experiments can be used to detect binding or to determine binding constants and epitope maps. Epitope mapping refers to determining the functional groups of the ligand that are in closest contact with the protein. Epitope mapping information can be used to guide the design of ligands or to gather information about the binding mode of the ligand to the protein.

Exchange in Ligand-Detected Experiments

For ligand-detected ligand–protein binding experiments, the exchange must be fast on the chemical shift timescale. Fast exchange is necessary because it is the free ligand resonances that are detected; therefore, the exchange must be fast enough such that the ligand samples both the

bound and free state over the course of the experiment. The fast exchange requirement sets an approximate lower limit on detectable binding constant (K_D) in the nanomolar range. The upper limit for the detectable K_D can be tuned by changing the concentration of the ligand according to eqn [3].

Saturation Transfer Difference

The saturation transfer difference (STD) experiment is performed by acquiring two one-dimensional (1D) NMR spectra that are then subtracted to create the STD spectrum, thus the 'difference' in the name of the experiment. The protein is saturated by an initial train of 90° Gaussian pulses that alternate on successive scans between 'on-resonance' (selectively saturating protein resonances) and 'off-resonance' (far outside the spectral window) spectra. The two sets of spectra are collected in an interleaved format to minimize artifacts that result from any instrumental instability during the course of signal averaging. The selective saturation is followed by a 90° hard pulse that can be followed directly by signal acquisition, but often is followed by a filter to suppress any remaining protein signals and water suppression.

Although only some of the protein resonances are directly excited by the presaturation pulse train, saturation spreads quickly throughout the protein due to spin diffusion. Any ligand bound to the protein during the saturation period will also become saturated by spin diffusion from the protein while bound. Resonances will be observed only in the STD spectrum for those compounds that lose some of their signal intensity in the 'on-resonance' spectrum due to receiving saturation from the protein.

In addition to identifying binding ligands, the STD experiment can be used to generate an epitope map. Regions of the ligand molecule that come into closer contact with the protein will experience more cross relaxation and therefore will have greater signals in the STD spectrum. The epitope map is generated by calculating for each ligand resonance a measure of relative intensity in the on- and off-resonance spectra (I_{on} and I_{off}), known as the STD factor.

$$\text{STD factor} = \left(\frac{(I_{off} - I_{on})}{I_{off}} \right) \times 100 \quad [4]$$

Therefore, a larger STD factor indicates the proton is nearer the protein. Epitope maps can be accurately generated only if exchange of the ligand between the free and bound states is fast enough such that spin diffusion does not spread the saturation from the protein throughout the ligand while the ligand is bound. Also, T_1 relaxation times usually vary within the ligand and care must be taken to choose a saturation time, usually approximately 1 s or less, such that the STD factors for the

ligand protons will be ordered according to their distance to the protein rather than their T_1 relaxation time. Another caveat is that although spin diffusion is thought to evenly saturate the protein resonances, this is not always the case and the resultant epitope map can be influenced by the choice of saturation frequency.

Diffusion

Diffusion experiments can be used to measure ligand-protein binding constants, or generate epitope maps. Determination of the diffusion coefficient is required for calculating binding constants. The signal intensity, I , decay from a series of 1D NMR spectra in which the amplitude of magnetic field gradients, g , are increased is fit by eqn [5] to determine the diffusion coefficient, D :

$$I = I_o \exp[-D(\delta\gamma g)^2(\Delta - \delta/3 - \tau/2)] \quad [5]$$

In eqn [5], I_o is the resonance intensity in the absence of gradient pulses, γ the gyromagnetic ratio of the observed nucleus, δ the duration of the gradient, Δ the diffusion time, and τ is the gradient recovery time.

The observed diffusion coefficient, D_o , determined from eqn [5] for a ligand in a protein-ligand solution is a weighted average of the ligand diffusion coefficient while free in solution (D_f) and the ligand coefficient while bound to the protein (D_b), as described by eqn [6]:

$$F_f D_f + F_b D_b = D_o \quad \text{where } F_f + F_b = 1 \quad [6]$$

In eqn [6], F_b is the fraction of the ligand that is bound to the protein and F_f is the fraction that is free in solution. The free ligand diffusion coefficient can be obtained from a solution of ligand in the absence of protein (corrected for the viscosity differences between the solutions). The bound diffusion coefficient is assumed to be the diffusion coefficient of the protein, which can be measured for a solution containing only the protein. Equations [6] and [2] can be combined to generate an expression for the binding constant, K_d , made up entirely of known or measurable quantities:

$$K_d = P_{\text{tot}} \left(\frac{D_b - D_o}{D_o - D_f} \right) + L_{\text{tot}} \left(\frac{D_o - D_b}{D_b - D_f} \right) \quad [7]$$

In eqn [7], P_{tot} is the total protein concentration, L_{tot} the total ligand concentration, and the diffusion coefficients are as in eqn [6].

Another use of diffusion experiments is to generate epitope maps. Magnetization can exchange by NOE during the diffusion delay period and results in the deviation of the diffusion decays from pure exponential behavior. An epitope map is generated by first fitting a second-order polynomial to the plot of natural log of signal intensity versus the square of gradient amplitude.

The coefficient of the squared term in the polynomial, usually referred to as κ , is used as a measure of how much the curve deviates from linearity. The diffusion decays for atoms in closer contact with the protein will be more curved as a result of participating in more magnetization exchange with the protein, and therefore a greater κ value will be obtained from the second-order polynomial fit.

WaterLOGSY

WaterLOGSY (water–ligand observed with gradient spectroscopy) like STD relies on selective saturation. However, instead of selectively saturating a portion of the protein NMR envelope, the water resonance is selectively saturated. The preferred WaterLOGSY pulse sequence is the e-PHOGSY pulse sequence. In the first part of the pulse sequence, the bulk water is selectively excited whereas other magnetization is dephased. This is followed by storage of the bulk water magnetization along the z -axis during a mixing time in which magnetization exchange occurs between the water and the ligand. Following the mixing time, the magnetization is returned to the transverse plane, the water signal is suppressed, and finally the remaining signal is acquired. The pulse sequence is phase cycled such that signals in the resulting spectrum are only due to an NOE enhancement.

There are several routes by which magnetization can be transferred from bulk water to the ligands. Any magnetization transferred through the protein or directly from bound water molecules results in negative NOE enhancement. Negative NOE enhancements can easily be differentiated from positive enhancements observed for nonbinding ligands, which only exchange magnetization with waters of solvation or through exchangeable protons.

NOESY

There are several applications of 2D NOESY experiments to investigate protein–ligand binding. A 2D NOESY experiment can be used to determine protein–ligand contacts. Because NOE cross relaxation occurs between ligand and protein while bound, cross peaks between ligand and protein NMR signals can be observed in a 2D NOESY spectrum of a protein–ligand solution. These intermolecular cross peaks are indicative of binding, but they can be difficult to observe in the presence of intramolecular cross peaks that may result from both ligand and protein. Although NOESY cross peaks are not generally used to generate quantitative epitope maps, qualitative information about the types of residues and which areas of the ligand molecule are involved in the binding interaction can be obtained.

Intermolecular NOESY cross peaks can also be detected between multiple ligands that bind competitively to a protein as in the INPHARMA (inter-ligand NOE for pharmacophore mapping) method. The transfer between the competitive ligands is protein mediated, meaning the magnetization transfers from one ligand to the protein and then to the second ligand that binds only after the first ligand dissociates from the protein. The result of this stepwise transfer of magnetization is negative cross peaks between resonances of the two ligands. Thus, if the binding orientation of one of the ligands is known by other means, the results of docking calculations for the other ligand can be evaluated in the light of the intermolecular cross peaks.

Alternatively, intermolecular NOESY cross peaks between multiple small ligands can occur due to direct cross relaxation while both ligands are bound to the protein. Again, the cross peaks will be negative because the magnetization exchange occurred while the ligands were bound to the protein. The cross peaks that result from both ligands being colocated within the binding pocket can be used to ‘grow’ larger, more strongly binding ligands by combining smaller weakly binding fragments.

Another example of the use of NOESY experiments to investigate protein–ligand binding is transferred NOE (trNOE or trNOESY). In trNOE experiments, ligand intramolecular cross peaks are used to determine the bound conformation of the ligand. Although resulting from the small molecule ligand, the trNOE cross peaks will be negative because the NOE is transferred from the bound ligand to free ligand by chemical exchange between the bound and free states during the experiment. The ligand takes on the motional properties of the protein while bound (τ_c). Therefore, any NOE that builds up between ligand protons while bound will result in a negative enhancement. The free ligand retains the NOE information from the bound state because the free ligand τ_c usually places it in the positive or nearly the null region of the NOE curve; therefore, the NOE will build up more slowly toward a smaller maximum. Understanding the bound ligand conformation can help with modeling and optimization efforts.

Relaxation Techniques

Relaxation techniques take advantage of the difference in correlation time (τ_c) for the free ligand and the bound ligand. The transverse relaxation rate constant R_2 ($R_2 = 1/T_2$) is directly proportional to τ_c and line width (full width at half maximum = R_2/π). Thus, the resonances of ligands that bind the protein will be broadened in a spectrum of a protein–ligand solution as compared to a spectrum of a free ligand solution. A special case of the use of relaxation techniques is ^{19}F NMR-based screening

where the broad chemical shift range and large chemical shift anisotropy cause very large changes in line widths between the free and bound ligands.

Experimental Requirements

There is no upper limit on the size of the protein in ligand-detected experiments, and large targets are more desirable than smaller ones. The differences in relaxation and diffusion coefficients between the target and the ligand are greater when the target is larger. Also, spin diffusion within the protein and from the protein to the bound ligand is more efficient when the target is large. The STD experiment requires the lowest protein concentration (approximately single-digit micromolar concentrations) because, under fast exchange conditions, the saturated ligand population builds up during the saturation period. Because the relaxation of the ligand magnetization is much slower when free, the ligand that has already visited the bound state can retain the saturation during the rest of the saturation time whereas other ligands bind to the protein and become saturated. However, for diffusion experiments and relaxation experiments that detect an averaged effect, the ligand excess must remain low such that the bound state makes a significant contribution to the observed diffusion coefficient or relaxation time. Therefore, for these types of experiments, the protein concentration must be much higher, on the order of tens to hundreds of micromolar.

Protein Background Suppression

Because ligand-detected experiments rely on the detection and measurement of ligand signals, suppression of protein background signals is usually required. This is especially true for diffusion experiments since the ligand-to-protein ratio must be kept low and unsuppressed protein resonances contribute more to the measured ligand resonance integral as the gradient amplitude is increased.

The protein resonances can be selectively suppressed by the incorporation of a filter into the pulse sequence to filter the protein resonances from the ligand resonances by differences in either T2 (CPMG pulse train) or T_{1ρ} (T_{1ρ} spinlock). The length of the pulse train or spinlock must be carefully optimized because there is a tradeoff between sensitivity and suppression as the ligand resonance intensity will also be somewhat reduced by protein background resonance suppression. Also, keeping the magnetization transverse while the protein signal decays will cause J-modulation artifacts on the ligand resonances, which further degrades the quality of the spectra.

Example Application

The SHAPES library (a small library of approximately 120 small compounds whose average molecular weight is 194 Da), which was designed to represent the most common drug frameworks with commercially available compounds, was screened against the p38 MAP kinase. The initial screen was conducted using 1D spectra to observe line broadening of the small molecule resonances on binding to the kinase and 2D NOESY techniques to observe trNOE cross peaks for binding molecules. The identified weakly binding bicyclic molecules (**Table 1**) contained imidazole or a related heterocycle bound to another aryl ring. Diffusion experiments were used to determine that the initial hits bound to p38 MAP kinase with single-digit micromolar affinity. Because imidazole was not identified as a hit in the initial screen, the imidazole formed the core of the molecule and was substituted with other aryl substitutions. The resulting tricyclic follow-up compounds exhibit improved *K_d* by an approximate order of magnitude (**Table 1**). The follow-up compounds were further combined to produce the lead-like compound shown in **Table 1** that is of the same class as a previously discovered and well-characterized SmithKline Beecham inhibitor of p38 MAP kinase.

Target-Detected Experiments

Target-detected protein–ligand binding experiments rely on detecting chemical shift perturbations of protein resonances on ligand binding. Because these perturbations of the chemical shift will generally be greater for the residues near the bound ligand, the binding pocket can also be identified using target-detected experiments. In addition, the relative position of the binding pockets for different hits or inhibitors can be mapped, which can be used to link together hits from fragment-based screening schemes.

Exchange in Target-Detected Experiments

The exchange requirements on target-detected experiments are less stringent because these experiments do not rely on the detection of free ligand. Therefore, target-detected techniques can be used to study protein–ligand binding that is tighter (slower off-rate) than is possible for ligand-detected techniques. Equation [2] still applies and therefore the ligand concentration will determine binding constant limitations.

Chemical Shift Perturbation

Perturbations of the target chemical shifts in 2D spectra in the presence and absence of ligand are indicative of binding. For comparison, a control spectrum of protein without ligand is acquired. To control for the effect of

Table 1 Results of screening SHAPES library and hit-to-lead progression against p38 MAP kinase*Initial hits**Tricyclic follow-up compounds**Lead-like compound*^aEstimated from line broadening and trNOE measurements.^bDetermined enzymatically.

adding a small amount of solvent to the solution when the ligand is added, the control spectrum is often acquired with a dummy spike – a spike of only solvent or buffer solution. The control spectrum is then compared to a spectrum of the protein in the presence of ligand. A change in the chemical shift of the protein cross peaks in the presence versus the absence of ligand is indicative of ligand binding. These changes (if localized over a small region of the protein) can be mapped onto the previously determined protein structure to determine the binding site.

The most well-known approach to target-detected screening is SAR (structure–activity relationships) by NMR. In the SAR by NMR approach ¹⁵N and ¹H chemical shifts of a labeled target are observed in 2D heteronuclear single-quantum correlation (¹H–¹⁵N-HSQC) experiments in the presence and absence of ligand. The two HSQC spectra are then compared. Perturbations of either the ¹⁵N or the ¹H chemical shifts indicate ligand binding, and after peak assignment, these

can be mapped onto the protein structure to locate the binding site. Analogs of the initial hit are synthesized to optimize the ligand for the binding site. The results of the initial screen can direct the synthesis of analogs since functional groups can be added to specifically interact with neighboring amino acid residues. Next, a hit that binds at a binding site nearby the optimized ligand is identified either by another screen in the presence of a saturating amount of the optimized ligand or by further analysis of data obtained in the first screen. The second ligand is then optimized for its binding site. Using information about the locations and residues involved in the two binding sites and the orientation of the two fragments, a series of compounds is synthesized linking the two identified molecular fragments. The goal is to identify a high-affinity ligand generated by combining weaker affinity ligands. The affinity of the high-affinity ligand should be the product of the two weaker ligand affinities in addition to a term to account for the affinity changes due to linking the ligands.

Two main limitations of target-detected protein–ligand binding techniques are spectral crowding and issues with excessively broad lines. Transverse relaxation-optimized spectroscopy (TROSY) addresses one of these limitations by reduction of the observed line width of protein resonances. This reduction in line width expands the applicable protein size range for target-detected experiments to approximately 100 kDa. To get the best spectra from TROSY experiments, deuteration of the protein is often required because other protein protons provide an efficient relaxation mechanism causing line broadening. The overall effect of the application of the TROSY pulse sequence is to produce a coupled spectrum in which phase cycling has been used to select the sharpest component from the four-component cross peak that would appear in a coupled ^1H – ^{15}N correlation experiment.

The other limitation of target-detected protein–ligand binding techniques, crowded spectra, can be addressed with selective labeling. Only labeling the residues in the active site of the protein or only labeling certain amino acid pairs within the protein limits the total number of peaks in the spectrum, alleviating spectral crowding for larger proteins or allowing multiple targets to be screened in one experiment as in the strategy known as RAMPED-UP NMR.

Experimental Requirements

Labeling of the protein is required for all target-detected protein–ligand binding experiments. Depending on the experimental scheme chosen, one or more of the following types of labels may be needed: ^{15}N , ^{13}C , or ^2H . Target-detected screening experiments require that the target protein is small, usually on the order of 30 kDa or less, so that there is great enough spectral resolution to detect specific protein resonances and determine the protein tertiary structure before performing screening experiments. However, as discussed in the previous section, with the use of the TROSY experiment, this useful range can be extended up to approximately 100 kDa. Protein concentrations in the hundreds of micromolar range are required for target-detected experiments to yield spectra in reasonable amounts of time. This also highlights the necessity that the protein be highly soluble to achieve such high protein concentrations.

Example Application

A screen of a compound library of 11 520 compounds against the N-terminal domain of human HSP90 was conducted by monitoring chemical shift changes of methyl groups of the Leu, Val, and Ile in the presence of library compounds in 2D $^1\text{H}/^{13}\text{C}$ HSQC experiments. Hit compound 1 was identified from the initial screen with a K_d of 20 μM , and a second screen in the presence of saturating amounts of 1 was performed. From the

second screen, compound 2 was identified with a K_d in the presence of 1 of 150 μM . The structure of the ternary complex of compounds 1, 2, and the N-terminal domain of HSP90 was solved by both X-ray and NMR and are shown in **Figure 1(a)** and **1(b)**. In the X-ray structure (**Figure 1(a)**), compounds 1 and 2 are π -stacked in a small binding pocket. However, in the NMR structure (**Figure 1(b)**) the binding pocket is more open and the orientations of 1 and 2 are dramatically different in this open form of the binding pocket. In the NMR structure, the CF_3 group is pointed toward the edge of the phenyl group of compound 2 and the furanone of compound 2 is pointed toward L107. Compounds were synthesized linking compounds 1 and 2 with linkers that will accommodate the relative orientations of the two initial hit compounds. Compounds 3 and 4 were identified with K_i of 1.9 and 4.0 μM , respectively (see **Scheme 1**). Further, X-ray structures of compounds 3 and 4 bound to HSP90 (**Figure 1(c)** and **1(d)**, respectively) confirm that the linked compounds bind the target as intended.

Comparison of Ligand-Detected and Target-Detected Experiments

Ligand-detected experiments have the advantage that they are easily applicable to most systems in which the protein and ligand are both soluble. Target-detected experiments, however, are limited to systems in which the target is small or cases where it is possible to use a small part of a larger target. Even if the target is of the appropriate size, flexibility of the protein especially near the binding pocket can preclude the use of target-detected experiments due to difficulty detecting the target resonances. Target-detected experiments can be used to screen for tighter binders as compared to ligand-detected experiments due to the fast exchange requirement for ligand-detected experiments. Epitope maps determined from ligand-detected experiments can be used to determine which parts of the ligand are interacting more or less strongly with the protein, giving hints as to where to functionalize hits to increase binding affinity. However, only target-detected experiments can give information about what types of functional groups would be best because target-detected experiments can be used to identify amino acid residues near the binding pocket. Ligand-detected experiments require less protein for screening as compared to target-detected screening approaches and do not require labeling, both of which can be very important considerations if the protein is difficult to express or isolate. Also, when screening a single target against a cocktail of ligands, it is more convenient to identify the hit from a mixture based on the changes to ligand resonances, whereas target-detected experiments require a lengthier deconvolution

process. However, information from initial screening using target-detected experiments can be used further for computational studies to direct lead optimization (e.g., see SAR by NMR discussion in the section on chemical shift perturbations).

Screening

NMR-based screening techniques, rarely used in isolation, are usually a piece of an overall screening strategy that may include HTS, screening by other techniques such as X-ray diffraction, and quite often, computational techniques. NMR-based screening can be used as the primary screen to discover initial hits, a follow-up and confirmatory screen, or to direct hit-to-lead progression.

Screening Library

Screening an appropriate library is central to the success or failure of any overall screening strategy. Therefore, copious time and effort is usually exerted before implementation of the screening experiments, to develop a library that is positioned for success. Several methods for developing a library of compounds exist. Owing to lower throughput and higher reagent demand, the libraries designed for NMR screening are generally smaller and more focused than libraries designed for HTS. These libraries will often, unlike most HTS libraries, be composed of smaller fragments that would be expected to bind to the target only weakly but be more synthetically amenable.

Fragment-Based Screening

Fragments are very small molecules (molecular weight 100–300 Da). Fragment-based screening takes advantage of the strengths of NMR-based screening techniques for detecting weak binding. The lower throughput of NMR-based screening techniques becomes less problematic with fragment-based screening methods. The effective library size is much larger than the number of fragments in the library if multiple fragments are used to construct the lead molecule. The advantage of fragment-based screening is that weakly binding fragments can be used to build a larger stronger binding compound instead of finding a tight binder that may need to be deconstructed during optimization. Both of the application examples discussed in this article are examples of fragment-based screening in which small fragments are first screened and the hits in initial screens are combined to generate larger stronger binding lead compounds. Combine the fragment-based screening with the additional information NMR spectroscopy yields, as compared to other screening techniques, and the power of NMR-based screening is revealed.

$\Delta\theta$	laser beam divergence
$\Delta\lambda$	spectral line width, wavelength
$\Delta\nu$	spectral line width, frequency

$\Delta\nu_D$	Doppler line width
τ	lifetime
θ_i	angle of incidence
θ_r	angle of reflection
θ_B	Brewster angle
θ_c	critical angle
θ_i	angle of diffraction
θ_t	angle of refraction
λ	wavelength of light
Λ	grating period
ν	frequency of light
ν_{12}	transition frequency
ν_q	frequency of longitudinal cavity mode
σ	Stefan–Boltzmann constant
i	diffraction-order integer
τ_p	pulse length
ω	angular frequency of light
ϕ	phase

Optics

Light

Light emanates from sources with a wide variety of physical embodiments. Examples include the Sun, a sodium arc lamp, an incandescent light bulb, and a helium–neon laser. The physical processes producing light emission appear to be distinctly different for each type of source. On a fundamental level, however, light is generated as a result of acceleration of electric charges. Thus, a synchrotron generates light by accelerating free electrons in a circular storage ring. An incandescent light bulb radiates as a result of electric-current-induced electronic charge vibrations and subsequent emission of radiation. A laser operates under atomic transitions involving bound charges acting as miniature, light-radiating electric dipole antennas.

Electromagnetics

Light propagates as an electromagnetic wave. Maxwell's equations govern the propagation of light and other electromagnetic waves in free space, in material media, at interfaces, and through apertures. Visible light has wavelengths, λ , expressed in nm or μm ($10^3 \text{ nm} = 1 \mu\text{m} = 10^{-6} \text{ m}$), or frequency, ν , in Hz or s^{-1} , detectable by the human eye typically falling within the $380 < \lambda < 780 \text{ nm}$

Figure 1 A snapshot of an electromagnetic plane wave with wavelength λ illustrating its spatial characteristics. The electric-field component e_x and the magnetic-field component h_y oscillate in phase but orthogonal to each other and to the direction of propagation. This wave is said to be linearly polarized along the x -direction.

range. The electromagnetic spectrum includes the ultra-violet (UV) region often defined to be $10 < \lambda < 380$ nm and the infrared (IR) region $780 \text{ nm} < \lambda < 1 \text{ mm}$, also of great importance in optics and spectroscopy.

Maxwell's equations yield a wave equation that predicts the propagation of electromagnetic radiation. The most elementary solution is the plane wave expressible as a function of space (x, y, z) and time (t) as

$$e(z, t) = \hat{x}e_0 \cos[\omega t - kz + \phi] \quad [1]$$

This wave, propagating in the $+z$ direction, is monochromatic with angular frequency $\omega = 2\pi\nu$, wavenumber $k = 2\pi/\lambda$, and with $\lambda\nu = c$, where c is the speed of light in the medium in which the wave propagates. An arbitrary phase factor ϕ is included. This wave, expressed in terms of the electric field vector $e(z, t)$, has amplitude e_0 and is linearly polarized along the x direction, with $\hat{x}$ denoting a unit vector. An electromagnetic plane wave is a transverse wave without any field component along the direction of propagation. With $e(z, t)$ representing the electric field (V m^{-1}), Maxwell's equations require that an orthogonal magnetic field (A m^{-1}) vector $b(z, t)$ also be associated with the wave as shown in **Figure 1**. Since $e_0 = \text{constant}$, the plane wave is transversely infinite and thus carries infinite energy; it is further infinite in time and exists everywhere in space. In spite of these idealizations, the plane-wave model is exceedingly successful in predicting a large range of optical phenomena such as reflection/refraction at metallic and dielectric interfaces, diffraction by spectroscopic gratings, wave propagation in nonlinear and anisotropic media, etc. A practical, transversely finite, laser beam may be 1 mm in diameter which is 2000λ for $\lambda = 500 \text{ nm}$; it is well approximated as a plane wave since it is wide on the scale of λ .

Polarization

The vectorial nature of the electromagnetic fields representing light implies polarization, a fundamental property of light. The particular orientation of the e -vector of a

plane wave incident on an interface has a profound effect on the detailed interaction that takes place and influences, for example, the amount of light that is reflected or transmitted. If the electric field vector is confined to oscillate in a plane (e.g. the X - Z plane in **Figure 1**), the wave is said to be linearly polarized. If the tip of the electric field vector traverses an elliptical path around the direction of propagation, the state of polarization is elliptical. Circular polarization and linear polarization are special cases of the general state of elliptical polarization.

The influence of the state of polarization is illustrated in **Figure 2** where a polarized plane wave in air (refractive index, $n_1 = 1$) is incident on a piece of glass ($n_2 = 1.5$). The index of refraction is defined as $n = c_0/c$, where c_0 is the speed of light in vacuum. For s-polarized light, with the e -field oscillating orthogonal to the plane of incidence as shown, the reflectance (R_s , defined as the ratio of optical power density (W cm^{-2}) reflected to that of the input wave) increases monotonically as the angle of incidence, θ_i , is increased. For a p-polarized incident wave, the reflectance, R_p , differs markedly, even exhibiting a reflection zero when $\theta_i = \theta_B$, which defines the Brewster angle given by $\theta_B = \tan^{-1}[n_2/n_1]$. The angle of incidence θ_i is related to the angle of refraction θ_t by Snell's law $n_1 \sin \theta_i = n_2 \sin \theta_t$ which holds for both polarization states. Additionally, the angle of reflection is $\theta_r = \theta_i$. If the wave traverses a rare-to-dense interface ($n_1 < n_2$) then $\theta_t < \theta_i$. Conversely, if $n_1 > n_2$, $\theta_t > \theta_i$. In particular, for θ_i such that $\theta_t = 90^\circ$, total internal reflection occurs and $R_s = R_p = 1$ for all $\theta_i > \theta_c$, which is the critical angle given by $\theta_c = \sin^{-1}[n_2/n_1]$. Light propagation inside optical fibres in telecommunications systems occurs under conditions of total internal reflection.

Diffraction Gratings

Diffraction Gratings are widely applied on account of their dispersive properties. Thus a beam of polychromatic light incident on a grating spatially separates according to its spectral content. A diffraction grating with period A larger than the wavelength generally exhibits multiple diffracted waves excited by a single incident plane wave as illustrated in **Figure 3**. Diffraction gratings operate in reflection or transmission. In spectroscopic devices, such as monochromators, reflection gratings play key roles.

With reference to **Figure 3**, the grating equation describes the spatial division of the incident wave of wavelength λ into distinct directions θ_i for each order ι as

$$A(\sin \theta_i + \sin \theta_\iota) = \iota \lambda \quad [2]$$

where $\iota = 0, \pm 1, \pm 2, \dots$ labels the order of diffraction. Essentially the directions θ_i correspond to conditions of constructive interference of waves emanating from the grating facets. For a polychromatic incident wave, each

Figure 2 Light reflectance as a function of the angle of incidence of a planar air–glass interface. The influence of the state of polarization of the incident plane wave is illustrated.

Figure 3 Illustration of the dispersion properties of a surface-relief reflection grating. The monochromatic incident wave is diffracted into several waves propagating in directions specified by the grating equation. A change in the wavelength, λ , of the incident wave will alter the directions θ_i of the diffracted orders. Spectroscopic instruments often employ the first order ($i = 1$) to characterize the spectral content of the input light.

component wavelength propagates into directions specified by eqn [2]. Taking θ_i constant and differentiating, this angular dispersion is

$$\frac{d\theta}{d\lambda} = \frac{1}{\Lambda \cos \theta_i} \quad [3]$$

Thus, the angular spread per unit spectral interval is largest for higher-order (i) diffracted waves, small grating periods (Λ), and large diffraction angles (θ_i).

The diffraction efficiency, DE_i , specifies the optical power carried by the diffracted waves normalized with the power of the incident wave. For the surface-relief reflection grating of **Figure 3** with a square-wave profile,

Figure 4 The basic elements of a monochromator. The input spectrum contains wavelengths in the range $\lambda_1 < \lambda < \lambda_2$. The grating spreads the light within the diffraction orders (say $i = 1$) in which the instrument is operated. No other diffracted orders are shown in the drawing for clarity. The width of the slit defines the spectral content of the output light. Reproduced with permission from Oriel Corporation (1989) *Oriel 1989 Catalog*, Volume II.

the diffraction efficiency is given by

$$DE_i = (2/\pi)^2 \sin^2(2g) \quad i = 1, 3, 5, \dots \quad [4]$$

where $g = \pi n_1 d / \lambda \cos \theta_i$. This grating obtains a maximum DE_i of 40.5%. A lossless grating with a sawtooth (blazed) profile has a theoretical maximum DE_i of 100%.

Monochromators

A typical monochromator is schematically illustrated in **Figure 4**. The input light contains a range of wavelengths that are spatially separated with the diffraction grating as

Figure 5 Spectral characteristics of blackbody radiation. The spectral radiant emittance is plotted as a function of the wavelength for several values of the absolute temperature. The slanted, dashed line indicates Wien's displacement law.

shown. The exit slit controls the spectral content of the output light by blocking the undesired wavelengths surrounding the central one. The spectrograph is a similar instrument but without a slit. In this case, the output spectrum is picked up by a detector array such that a prescribed spectral band can be associated with a given detector element.

Thermal Sources

Thermal sources supply light by heating the source material to a sufficiently high temperature. If an electric current is passed through a filament made of a metal with high melting point such as tungsten, the filament glows. Thermal radiation exhibits a characteristic, spectrally broad, continuous emission spectrum. The laws of blackbody radiation are useful for describing the emission spectra of thermal, or incandescent, sources. A blackbody consists of an ideal material that completely absorbs all incident radiation independent of wavelength. Conversely, the maximum radiation emitted by a hot solid material at a given temperature is that of a blackbody. The radiation properties of a blackbody are determined completely by the absolute temperature.

In practice, the characteristics of a blackbody can be obtained approximately by a cavity with a small hole in its side. Radiation entering the cavity through the hole is completely absorbed. As the cavity is heated, blackbody radiation emerges from the hole.

Planck's radiation law gives the spectral distribution of blackbody radiation. It may be expressed as

$$M_\lambda(T) = C_1 \lambda^{-5} [\exp(C_2/\lambda T) - 1]^{-1} \quad [5]$$

where M_λ is the spectral radiant emittance given in W cm^{-2} per unit wavelength. Thus M_λ is the radiated power density per wavelength, λ . Further, T is the absolute temperature (K), $C_1 = 3.7418 \times 10^{-12} \text{ W cm}^2$ and $C_2 = 1.4388 \text{ cm K}$. These coefficients are expressed in terms of fundamental physical constants as $C_1 = 2\pi^5 h^2 c_0^2 / 15$ and $C_2 = hc_0/k_B$, where h is Planck's constant and k_B is Boltzmann's constant. **Figure 5** and **Figure 6** illustrate Planck's law on logarithmic and linear scales demonstrating the shift of the emission peak to shorter wavelengths with increasing temperature as well as increase of the radiated power density.

Taking $dM_\lambda/d\lambda = 0$ yields the wavelength, λ_{peak} , at which the radiation peak occurs; this obeys the relationship $T \lambda_{\text{peak}} = 0.28978 \text{ cm K}$, which is Wien's displacement law traced by the dashed line in **Figure 5**. Finally, calculating the integral

$$M = \int_0^\infty M_\lambda d\lambda = \sigma T^4 \quad [6]$$

gives the total power per unit area, M , emitted by the blackbody, where the Stefan-Boltzmann constant $\sigma = 5.6703 \times 10^{-12} \text{ W cm}^{-2} \text{ K}^{-4}$.

As the temperature of the blackbody increases, its colour changes as evident in **Figure 5** and **Figure 6**. The colour of a blackbody is thus uniquely dependent on its temperature. Real sources such as tungsten lamps that have spectral distributions approximating those of blackbodies can be assigned a colour temperature at which the spectrum most nearly overlays that of the blackbody. Outside the Earth's atmosphere, the Sun can, for example, be approximated as a blackbody at 6200 K, which is, then, the Sun's colour temperature.

Figure 6 As for Figure 5 but with a linear wavelength scale.

Figure 7a shows the spectral distribution of an incandescent lamp fitted with a tungsten filament inside a quartz bulb enclosing a rare gas and a halogen. The spectrum is smooth with a colour temperature exceeding 3000 K containing a significant amount of near-infrared light.

Electric-Discharge Sources

Electric discharge denotes the excitation of atomic states in a gaseous medium on passing an electric current through the medium. An ordinary household fluorescent lamp is an example of an electric-discharge source. The lamp tube, coated on the inside with fluorescent phosphors, contains a mixture of a rare gas and mercury vapour. On application of sufficiently high voltage across the lamp's terminals, a low-pressure mercury arc forms. Thus, excited Hg atoms emit UV radiation (a particularly strong line exists at 253.7 nm) which is absorbed by the phosphor and re-emitted as visible light. The phosphor radiation spectrum is concentrated in the visible spectral region; it is smooth with several superimposed discrete lines originating in the Hg atoms.

By increasing the lamp's internal operating pressures and temperatures, high-intensity light can be produced. High-intensity discharge lamps are classified as mercury-vapour, metal-halide, or high-pressure-sodium types. In these sources, the discharge is contained in arc-tubes placed inside the lamp envelope filled with inert gas. Additionally, short-arc lamps, such as xenon and mercury-xenon lamps, are capable of power output in the multi-kilowatt region. Typical spectral characteristics of such sources are shown in Figures 7b and c.

Table 1 gives wavelength ranges and power levels of selected light sources.

Lasers

Key Characteristics

In contrast to light emitted by traditional thermal or luminescent sources, the laser beam is directional with all

Figure 7 (a) Spectrum of a 1000 W tungsten-halogen lamp. Reproduced with permission from Oriel Corporation (1994) *Oriel 1994 Catalog*, Volume II. (b) Spectrum of a 200 W mercury arc lamp. of its power confined within a narrow angular range. As the beam expands slowly on propagation, its divergence, $\Delta\theta$, is small, often of the order of a milliradian (mrad). A direct result of this confinement of laser power within a small angular region is the high value of laser brightness, or radiance, measured in watts (W) per unit area (cm^2) per solid angle (steradian, sr). A typical argon laser beam with 1 mm diameter and 1 mrad divergence carrying a power of 1 W has brightness of $\sim 10^8 \text{ W cm}^{-2} \text{ sr}^{-1}$, whereas a 100 W light bulb radiating uniformly into a solid angle of 4π obtains only $\sim 1 \text{ W cm}^{-2} \text{ sr}^{-1}$. In addition, laser light is highly monochromatic, meaning that the spectral wavelength spread, $\Delta\lambda$, is small. An associated property of monochromatic sources is temporal coherence; lasers are highly coherent sources. Further,

Table 1 Representative power levels and wavelength ranges for common light sources

Source material	Wavelength range (nm)	Rated power (W)
Mercury	200–2500	50–1500
Mercury–xenon	200–2500	30–5000
Xenon	200–2500	15–30 000
Deuterium	180–400	30
Sodium	400–800	250–400
Tungsten–halogen	240–2700	50–1000

lasers operate in continuous-wave (CW) or pulsed modes, and they may be polarized or unpolarized. While many lasers operate with fixed output wavelengths, some laser types are tunable over relatively large spectral regions. Finally, laser beams can be focused to tiny spots ($\sim 1\text{ }\mu\text{m}$ diameter) with extreme power densities obtainable even for CW lasers.

Applications

These unique characteristics of lasers make them exceedingly useful in numerous applications. Thus, lasers enable applications in diverse fields such as telecommunications, holography, spectroscopy, integrated optics, lithography, and medicine. Specific functions include alignment, distance measurements, holographic data storage, signal processing, image processing, velocity measurement, industrial process control, inspection, surgery, welding, fusion, and propagation of fibre-optic communication signals.

Atomic Laser Processes

The term ‘laser’ stands for ‘light amplification by stimulated emission of radiation’. This stimulated emission occurs on interaction between a photon propagating in the laser’s active medium and an atom in an excited state. The incident photon essentially stimulates the emission of an identical photon which joins the incident photon coherently at the same frequency and along the same direction. By viewing the photon as an electromagnetic wave packet, stimulated emission is a coherent wave process wherein the electromagnetic field of the incident photon drives the electrons of the excited atoms into coherent oscillation. The atom then undergoes energy level transition by radiating energy in the form of an optical wavefield that is spatially and temporally coherent with the incident, stimulating wavefield.

The fundamental laser process, thus, relies on quantum-mechanical energy levels in atomic systems. Media sustaining laser action possess discrete energy levels with discrete spectral components produced on transitions between particular levels. If the transition is from an upper level E_2 to a lower level E_1 , the emitted photon will have frequency given by

$$\nu_{21} = (E_2 - E_1)/h \quad [7]$$

where h is Planck’s constant. The transition energy is $\Delta E = h\nu = hc/\lambda$.

Suitable laser energy levels have been discovered in thousands of atomic systems occurring in a variety of media. For example, discrete electron energy levels of isolated Ne atoms, originating in the proton–electron Coulomb attraction, enable the ubiquitous HeNe laser. Vibrations of molecules with associated harmonic-oscillator type quantum levels are basic to the CO_2 laser. Organic dye molecules exhibit electronic, rotational, and vibrational energy levels on account of their size and complex structure. This provides a continuum of available transitions and yields broadband, tunable dye lasers. Semiconductor lasers operate on transitions based on energy-level bands that form on merging of the discrete levels associated with individual atoms in the solid.

In thermal equilibrium, an atomic system with N_1 atoms in level E_1 and N_2 atoms in $E_2 > E_1$ obeys the Boltzmann principle

$$N_2/N_1 = \exp[-(E_2 - E_1)/k_B T] = \exp[-h\nu/k_B T] \quad [8]$$

Therefore, in thermal equilibrium, $N_2 < N_1$ and, if ν is in the optical region, $N_2 \ll N_1$. Such a system is absorptive and not amplifying. To obtain the amplification effect associated with stimulated emission, an external pump mechanism is required to induce population inversion such that $N_2 > N_1$. Population inversion in the active laser medium is, thus, a nonequilibrium condition that enables lasing. The pumping approach employed depends on the laser medium. Optical flashlamps are used to invert some solid-state laser media (Nd:YAG, ruby), electric-current discharge is effective for many gas lasers (HeNe, argon), direct current injection pumps semiconductor lasers (GaAs, InP), and optical pumping with an auxiliary laser (e.g. argon laser) is used to operate dye lasers.

Figure 8 schematically illustrates a four-level laser system such as that for a Nd:YAG laser. Population inversion and lasing is established between levels E_2 and E_1 . The optical pump populates level E_3 that may be a broad range of closely spaced levels in practice. Decay from E_3 down to the metastable upper laser level E_2 may occur via radiative or nonradiative relaxation processes. Random radiative emission, or spontaneous emission, occurs without a stimulating electric field, in contrast to stimulated emission. Nonradiative relaxation implies energy transfer via lattice vibration also called phonon modes.

Spectral Content

Spontaneous transitions in laser media possess a finite spectral bandwidth $\Delta\nu$. The concomitant frequency distribution is described by a line shape function, $g(\nu)$,

Figure 8 A four-level atomic energy system.

taken to be normalized as

$$\int_{-\infty}^{\infty} g(\nu) d\nu = 1 \quad [9]$$

The function $g(\nu)$ determines the spectral characteristics of the laser gain coefficient in inverted media. Light emission and absorption are both spectrally governed by $g(\nu)$.

The functional shape of $g(\nu)$ is defined by the particular line-broadening mechanisms of the atomic systems that constitute the active medium. If the atoms in the collection are indistinguishable, that is each atom acts the same, the line broadening is said to be homogeneous. Lifetime broadening and collision broadening are examples of homogeneous broadening. Systems with distinguishable atoms suffer inhomogeneous broadening such as Doppler broadening and lattice-strain broadening.

Lifetime broadening is due to the finite lifetime of the excited atomic state. It can be modelled as an exponentially decaying oscillator of the form (cf. eqn [1])

$$e(t) = e_0 \exp(-t/\tau) \cos(\omega_0 t), \quad t \geq 0 \quad [10]$$

emitting a wave of frequency ω_0 during the lifetime τ . The frequency content of the decaying oscillator is found by applying a Fourier transform

$$F(\omega) = \int_{-\infty}^{\infty} f(t) e^{-i\omega t} dt \quad [11]$$

This leads to a normalized, Lorentzian, line shape function in the vicinity of $\omega \cong \omega_0 = 2\pi\nu_0$ expressed as

$$g(\nu) = \frac{\Delta\nu}{2\pi[(\nu - \nu_0)^2 + (\Delta\nu/2)^2]} \quad [12]$$

where $\Delta\nu = 1/\pi\tau$ is the line width (full width at half maximum, FWHM) of the lifetime-broadened system. This result applies to homogeneous broadening, where each atom in the collection is characterized by a band-spread $\Delta\nu$. Short pulses (τ small) yield broad spectra. Atomic collisions that interrupt the decay cause additional broadening by reducing the effective average value of τ .

Doppler broadening is a commonly cited example of inhomogeneous broadening. The atoms in a gas have a statistical distribution of velocities; the atoms are thus distinguishable by their differing velocities that correspond to different atomic resonance, or transition, frequencies. The resulting Gaussian line shape function is given by

$$g(\nu) = \frac{2\sqrt{\ln 2}}{\sqrt{\pi}\Delta\nu_D} \exp\{-[4 \ln 2][(\nu - \nu_0)/\Delta\nu_D]^2\} \quad [13]$$

where the FWHM line width is $\Delta\nu_D = 2\nu_0[2k_B T \ln 2 / mc^2]^{1/2}$, where m is the atomic mass. Thus, as expected, $\Delta\nu_D$ increases with increasing T and decreasing mass. For example, the HeNe laser is Doppler broadened with $\Delta\nu_D \sim 1.5$ GHz, whereas the Nd:YAG laser is homogeneously broadened with $\Delta\nu \sim 120$ GHz.

The line shape function $g(\nu)$ spectrally governs the rate of spontaneous and stimulated emission. The stimulated transition rate per atom is given by $W_i = \lambda^2 I_\nu g(\nu) / (8\pi n^2 h \nu \tau)$, where n is the refractive index and I_ν is the intensity (W cm^{-2}) of the monochromatic optical wave (at frequency ν) causing stimulated emission. The relation to laser gain is established by considering propagation along the z -direction in the laser medium, which can be described by

$$\frac{dI_\nu}{dz} = (N_2 - N_1)[(\lambda^2 g(\nu)) / 8\pi n^2 \tau] I_\nu \equiv \gamma(\nu) I_\nu \quad [14]$$

which defines the exponential gain coefficient. The solution is

$$I_\nu(z) = I_\nu(0) \exp[\gamma(\nu)z] \quad [15]$$

implying exponential growth of the laser radiation intensity for $\gamma(\nu) > 0$ or $N_2 > N_1$ (inverted medium) and a traditional decay if the system is absorbing, or non-inverted, in thermal equilibrium.

Basic Laser Components

Figure 9 illustrates the building blocks of typical lasers. The active medium (gas, solid, or liquid) is placed between two mirrors constituting an optical resonator. The back mirror is highly reflective with reflectance, R , approaching

Figure 9 Chief components of a laser.

100%. The front mirror (output coupler) is also highly reflective but with a finite value of transmittance, T , typically a few percent, to allow the useful output laser beam to emerge from the resonator. The resonator-cavity mirrors may be flat or curved. A laser with two flat mirrors is difficult to align as small misalignment causes the oscillating light wave, making multiple round trips, to walk off and leave the cavity. It is thus a marginally stable configuration. Improved design is obtained with curved mirrors confining the laser light energy efficiently within the resonator. In particular, two mirrors with long radii of curvature constitute a practical, stable laser cavity. The laser medium is pumped with an external source, also shown in **Figure 9**, to maintain the inverted atomic population needed for laser power amplification to occur. Pumping methods include optical pumping of solid state lasers with incoherent (e.g. xenon) flash lamps, electric-discharge pumping of gas lasers, and direct-current-injection pumping of semiconductor lasers and light-emitting diodes. Collisions can also play a role in achieving the population inversion. For example, in the HeNe laser, the electrical discharge (a few kV at a few tens of mA current) drives electrons that collide with He atoms, raising them to excited levels (2s level desired). The He atoms then interact with Ne atoms, raising them to 3s₂ levels by collision energy transfer. The resulting metastable state with a lifetime of a few microseconds radiates the familiar red photons with 633 nm wavelength.

Laser Modes

Laser oscillation can build up from noise or from a deliberately injected signal. Before lasing, spontaneous emission generates a flood of photons propagating in random directions. Those taking a path along the resonator axis are reflected back into the active medium (i.e. feedback) and initiate the stimulated emission and amplification process with power provided by the external pump. If the round-trip gain exceeds the round-trip loss, optical energy builds up in the resonator. Since the pump provides finite energy, this oscillating power buildup saturates with steady-state oscillation established when the round-trip gain equals the round-trip loss. Under these conditions, a steady beam may be emitted from the laser, since the useful output light power is taken as part of the loss.

Thus, laser oscillation occurs inside a resonator confining the laser light. The resonator defines the frequency

distribution and the spatial distribution of the output light. A resonator with planar mirrors separated by distance L supports longitudinal modes with discrete frequencies

$$\nu_q = q(c/2L), \quad q = 1, 2, 3 \dots \quad [16]$$

Adjacent modes are thus separated by $c/2L$. A laser will support those longitudinal modes of frequency ν_q that fall under the gain curve of the laser medium.

Figure 10a shows an example of atomic line and several longitudinal cavity modes with six modes having sufficient gain to oscillate, the rest being below threshold and not surviving. The spectral properties of the individual longitudinal modes can be understood by treating the resonator as a Fabry–Perot etalon. Their spectral width, $\delta\nu$, is given in terms of the resonator's free spectral range, $\text{FSR} = c/2L$, and its finesse, F , as $\delta\nu = \text{FSR}/F$. If each of the cavity mirrors has a reflectance R , the finesse is $F = \pi R^{1/2}/(1 - R)$.

Figure 11 depicts some of the main components in a large-frame laser such as a commercial argon–ion laser. The resonator supports multiple longitudinal modes as suggested by eqn [16]. The active medium, in the case of argon, supports multiple well-separated atomic lines any one of which, as shown in **Figure 10a**, can accommodate several longitudinal cavity modes. To select one of the atomic lines, a prism is inserted in the cavity as shown. By angularly tuning the prism, a principal line, or wavelength, is selected such that it emerges out of the prism at normal incidence on the high reflector. This line can then oscillate in the cavity with other lines cut off. To narrow the laser's spectrum further, an intracavity etalon is applied. The etalon is a planar Fabry–Perot cavity of thickness d_e with its $\text{FSR} = c/2d_e$, thus supporting multiple longitudinal modes separated by a much larger frequency spread than the laser cavity modes since $L \gg d_e$. The etalon is tuned by rotation and by varying its temperature. When an etalon mode coincides with one of the laser modes in **Figure 10a**, that mode oscillates by itself with the adjacent modes suppressed. The laser then oscillates in a single mode with a corresponding decrease in the output spectral line width and associated increase in its level of coherence. The laser in **Figure 11** is equipped with Brewster windows (see **Figure 2**) that force the laser to favour a single polarization state as indicated.

In addition to the longitudinal modes discussed, the laser resonator admits multiple transverse modes that appear as spatial intensity variations across the output laser beam as shown in **Figure 10b**. Such transverse electromagnetic (TEM) modes are labelled with subscripts that count the number of zeros along the (x, y) transverse directions. The most useful mode has no zeros and thus the TEM₀₀ mode is preferred. This mode is the ubiquitous Gaussian laser beam obtained when the laser

Figure 10 Spectral and spatial modes of a laser. (a) Atomic line enclosing several longitudinal resonator modes. (b) Transverse spatial modes of a laser beam. The fundamental TEM_{00} mode is the Gaussian laser beam profile. The arrows indicate the direction of the beam's electric field at a given instant of time.

Figure 11 Principal components used to optimize the performance of a laser. The prism selects a particular atomic line and the wavelength of operation. The etalon selects a longitudinal mode and increases the laser's coherence. Reducing the aperture diameter favours the Gaussian spatial mode. The Brewster windows polarize the beam linearly.

aperture in **Figure 11** suppresses higher-order transverse modes. With reference to **Figure 12**, the intensity of a Gaussian laser beam carrying a total power P is expressible as

$$I(r, z) = \frac{2P}{\pi w^2(z)} \exp\left(-\frac{2r^2}{w^2(z)}\right) \quad [17]$$

with $w(z) = w_0[1 + (z/z_0)^2]^{1/2}$, where $z_0 = \pi w_0^2/\lambda$, called the Rayleigh range, w_0 being the beamwaist radius occurring at $z=0$, and $r^2 = x^2 + y^2$. If a thin lens of focal length f , with the lens placed at the waist, focuses this Gaussian beam, the radius of the focal point is

$$w_f = w_0/[1 + (z_0/f)^2]^{1/2} \quad [18]$$

Often $z_0 \gg f$ which gives $w_f \sim f\lambda/\pi w_0$. As an example, with $f = 10$ mm, $\lambda = 0.5$ μm , and $w_0 = 0.5$ mm, $w_f \sim 3$ μm . If $P = 1$ W, this yields a power density at focus of ~ 3 MW cm^{-2} or ~ 3 kW cm^{-2} if $P = 1$ mW (e.g. a small HeNe laser). In view of these high power densities, laser safety is an important concern. Eye protective goggles matched to the laser's wavelengths should be worn when working with lasers.

Figure 12 Parameters of a Gaussian laser beam.

Pulsed Lasers

Generation of intense short pulses of light is of interest in many fields, including nonlinear optics and spectroscopy. Pulse lengths in the femtosecond region with pulse power levels of terawatts have been achieved. Two common methods for short-pulse generation, Q-switching and mode locking, are summarized in this section.

In Q-switching, the laser is prevented from oscillating with the pump running such that a large inverted population builds up in the cavity. Oscillation occurs on removal of the blockage thereby switching the cavity Q back to its normally high value. A short, powerful optical pulse develops as the available gain rapidly depletes, typically on nanosecond timescales. Q-switching is accomplished by placing electro-optic or acousto-optic modulators inside the cavity or, in a passive manner, with a saturable absorber. The passive approach is particularly simple; a saturable absorber (organic dye solution) becomes transparent when sufficiently high gain has developed thus permitting a high-intensity pulse to escape. As an example, a Q-switched Nd:YAG laser may deliver ~ 1 J energy per pulse with pulse length of $\tau_p \sim 5$ ns, power per pulse ~ 200 MW, and repetition rate of 10 Hz.

An ideal, inhomogeneously broadened laser oscillates on multiple longitudinal modes separated by $c/2L$ in frequency. These free-running modes oscillate independently

Table 2 Representative figures characterizing common lasers

Laser type	Wavelengths (nm)	Power	Beam dia (mm)	Divergence (mrad)	Output
Helium–neon	633, 1152	0.1–50 mW	0.5–3.0	0.5–6.0	CW
Argon–ion	351–529 several	5 mW–25 W	0.5–2.0	0.5–1.0	CW
Helium–cadmium	325, 442	1–50 mW	0.3–1.2	0.5–3.0	CW
Dye (Ar pump)	400–1000	to 5 W	0.5–1.0	1–2	CW, tunable
Nd:YAG	1064	0.1–500 W (ave)	1–10	1–10	Pulsed
Nd:YAG	1064	0.5–1000 W	1–10	1–10	CW
CO ₂	10 600	1–100 W	3–7	1–5	CW
GaAlAs	750–900	1–100 mW	Divergent output	Large, $\sim 30^\circ$	CW
InGaAsP	1100–1600	1–100 mW	Divergent output	Large, $\sim 30^\circ$	CW
Ti:sapphire (Ar pump)	700–1100	0.1–1 W	0.5–1	1–2	CW, tunable

with random, uncorrelated phases. If the phases (ϕ in eqn [1]) can be locked together, a periodic laser-pulse train is obtained as output light. To accomplish this, an electro-optic or acousto-optic switching element can be placed in the cavity. It is modulated with a period equal to the resonator's roundtrip transit time $T = 2L/c$. Optimum conditions for light buildup correspond to minimum loss, that is an open switch. This switching action tends to lock the phases of the longitudinal modes such that their interference creates a pulse that passes through the open switch without loss. Wide atomic line widths, $\Delta\nu$, enclosing a large number of longitudinal modes produce the shortest mode-locked pulses since $\tau_p \sim \Delta\nu^{-1}$. For example, Ti:sapphire lasers, with their broad line widths, provide short pulses, with $\tau_p \sim 100$ fs, average power ~ 100 mW, and output pulse rate of ~ 100 MHz being representative numerical data.

Table 2 provides numerical parameters for some common lasers.

Symbols

$A_f(\nu)$	contribution to the absorbance of transition f in a sample of perfectly aligned molecules
$E_U(\nu)$	absorbance (at frequency ν) with electric vector in the specified direction (U , V , etc.)
$ f\rangle$	final state
K_f	average cosine square value = $\langle \cos^2(U, M_{0f}) \rangle$
$\hat{M}$	electric dipole operator
M_{0f}	electric dipole transition moment
$\hat{O}$	generic operator
u	a direction in the molecule
U	laboratory axis, unique axis
ν	a direction in the molecule ($= x, y, z$)
V	laboratory axis perpendicular to U
W	laboratory axis perpendicular to U and V
$ 0\rangle$	initial state
ϵ	electric vector
ν	light frequency

Light absorption is not only characterized by energy and intensity, it also has directional properties. These are often overlooked, even when they might provide essential information. Such information includes assignments of electronic and vibrational transitions and information on molecular structure, conformation and association. The directional properties of individual molecules cannot be observed in isotropic samples but require samples that are non-isotropic or aligned.

Although a natural (nonpolarized) light beam is non-isotropic in nature, since its electric and magnetic vectors are located exclusively in the plane perpendicular to the direction of the beam, the directional properties of aligned samples may best be studied using linearly polarized light. The term ‘linear dichroism’ refers to the change in absorption that may often be observed for non-isotropic samples when the direction of polarization of the light is changed by 90° .

In reality, most light in nature is partially polarized – scattering produces polarized light and most light around us is scattered sunlight. Historians believe that the Vikings used the polarization of light from the blue sky as a navigational

aid when they travelled to North America approximately 1000 years ago. Similarly, except for common solutions, most naturally occurring samples are non-isotropic; this is especially true for samples with a biological origin. The first linear dichroism experiment was actually carried out on a dye-stained cell membrane in the 1880s.

The Transition Moment

Many observable properties in connection with electronic transitions between state $|0\rangle$ and $|f\rangle$ may be calculated from the two wavefunctions by means of an integral of the type

$$\langle 0 | \hat{O} | f \rangle = O_{0f} \quad [1]$$

where $\hat{O}$ is an operator describing the desired property. In many cases $\hat{O}$ is not a scalar but a vector or tensor. The operator that describes absorption probability, the electric dipole operator $\hat{M}$, is a vector. Thus the corresponding observable property, the transition moment M_{0f} , will also be a vector.

M_{0f} may vanish for reasons of symmetry; then the transition between $|0\rangle$ and $|f\rangle$ is said to be symmetry forbidden. For example, if the molecule possesses a plane of symmetry, the product of $\langle 0 |$, $\hat{M}$ and $|f\rangle$ will be either symmetric or antisymmetric with respect to the plane; if it is antisymmetric, the integral vanishes. The electric dipole operator $\hat{M}$ corresponds to the sum of charges on particles in the molecule times their coordinates and is therefore antisymmetric with respect to any symmetry plane, thus $\langle 0 |$ and $|f\rangle$ must have different symmetry properties with respect to the plane in order for the integral to be nonzero.

In molecules with symmetry elements, the direction of M_{0f} is determined by the symmetry of the two states $|0\rangle$ and $|f\rangle$. In the important cases of C_{2v} , D_{2h} and D_2 symmetric molecules, only three different excited-state symmetries can be reached by an electric dipole transition from a totally symmetric ground state. For example, in the case of D_{2h} , each of the three ‘allowed’ excited state types are antisymmetric with respect to one, and only one, of the three symmetry planes of the molecule. The direction of M_{0f} for the three different allowed transitions is in each

case perpendicular to the antisymmetry plane. For transitions to all other excited states, M_{0f} becomes zero; these transitions are said to be symmetry forbidden.

Production of Linear Dichroic Samples

Although many samples occurring in nature are partially aligned from the start, most linear dichroism experiments are performed on samples that have been aligned in the laboratory. Single crystals may be grown of many molecules: if the crystal structure is known and suitable, information may be obtained on transition moments for electronic and vibrational transitions. In practice, this is often experimentally difficult – very thin crystals are required for reasonably strong transitions and the interpretation of the spectra may be very complicated, primarily owing to strong intermolecular interactions in the crystal. Alignment in electric fields may be used, especially for large molecules (see the Kerr effect). Magnetic fields may be used to align molecules with permanent magnetic moments, but the effect is weak (see the Cotton–Mouton effect). Further details may be found in the article on linear dichroism instrumentation.

In the following we shall consider samples aligned either by photoselection or by dissolving the molecules in ‘anisotropic solvents’. Ordinary photoselection is not based on a physical alignment of a set of molecules. Instead a partially aligned subset of an isotropic molecular assembly is selected by absorption of natural or polarized light. Since the relative transition probability for molecules with different spatial orientations is known, the orientation distribution of molecules in the photoselected sample will often be known. To preserve this alignment, the molecules must be kept in a high viscosity solvent, usually at low temperature. Anisotropic solvents may be single crystals of a suitable host molecule, membranes, a fast-flowing liquid, aligned liquid crystals or stretched polymers. With the possible exception of the first of these solvents, the orientation distribution of the sample molecules is not known, but, as we shall see, a complete interpretation of absorption spectra is possible even when only a few, simple properties of this distribution are known.

Description of Molecular Alignment: One-photon Processes

The transition probability for linearly polarized light with its electric vector ϵ_U along sample (laboratory) axis U at the wavelength of the transition to state $|f\rangle$ in a single molecule is proportional to

$$(\epsilon_U \cdot M_{0f})^2 = (M_{0f})^2 \cos^2(U, M_{0f}) \quad [2]$$

where (U, M_{0f}) is the angle between U and M_{0f} . The sample axis U is usually chosen according to the

properties of the individual sample; most important samples are uniaxial (see below) and in these U is the unique axis. It is clear that the absorption depends on molecular alignment; if the molecule is aligned so that M_{0f} is perpendicular to U , the probability becomes zero, while the maximum absorption probability occurs when M_{0f} is parallel to U . In a typical partially aligned sample the angle (U, M_{0f}) may take on all possible values between 0° and 90° for individual molecules in the sample. This means that an average value over all sample molecules must be used and we obtain

$$\langle (\epsilon_U \cdot M_{0f})^2 \rangle = (M_{0f})^2 \langle \cos^2(U, M_{0f}) \rangle \quad [3]$$

where the brackets refer to average values for all molecules in the sample.

In the important case of a molecular symmetry (C_{2v} , D_{2h} and D_2) that only allows transition moments along three different perpendicular x , y and z directions within the molecule, we label the corresponding average cosine square values K_x , K_y and K_z :

$$\langle \cos^2(U, M_{0f}) \rangle = K_x, K_y \text{ or } K_z \quad [4]$$

for x -, y - or z -polarized transitions, respectively. These three K values are not independent; their sum is equal to 1, which often provides a useful test. Note, however, that K values are useful for any direction in a molecule, for example a low-symmetry molecule; the transition to state $|f\rangle$ will, for a given sample alignment, be characterized by the K value K_f :

$$K_f = \langle \cos^2(U, M_{0f}) \rangle \quad [5]$$

The molecular direction that corresponds to the largest possible K_f – in other words the direction that, on the average, is best aligned in the molecule with respect to U – is called the orientation axis. Since it is determined by averaging, the position of the orientation axis is not always obvious; as a result, the axis is sometimes called the effective orientation axis. In the symmetrical molecules mentioned above it will be one of the three directions determined by symmetry. It is often labelled z . The least well-aligned axis, with the lowest K value, is often called x and the intermediate axis is called y . The three axes are those that diagonalize a ‘ K -tensor’ with elements $\langle \cos(u, U) \cos(v, U) \rangle$, where u and v are directions in the molecule.

The orientational dependence of the two linear dichroism spectra can easily be expressed in terms of the K values. If the electric vector is along the U axis, we obtain for the resulting absorbance $E_U(v)$:

$$E_U(v) = \sum K_f A_f(v) \quad [6]$$

where the sum is over all relevant transitions f and $A_f(v)$ is equal to the contribution to the absorbance from transition f

in a sample of perfectly aligned molecules (this is also equal to three times the contribution from transition f to the absorbance of an isotropic sample). Similarly, if the electric vector is along the V laboratory axis, perpendicular to U , we obtain for the resulting absorbance $E_V(v)$:

$$E_V(v) = \sum K'_f A_f(v) \quad [7]$$

where $K'_f = \langle \cos^2(V, M_{0f}) \rangle$. The linear dichroism is equal to

$$LD(v) = E_U(v) - E_V(v) \quad [8]$$

Uniaxial Samples

The equations above are valid for any sample. Each transition moment direction is characterized by two quantities, K and K' . If the sample is uniaxial, that is all directions perpendicular to a given sample axis are equivalent, the equations simplify further. We chose U as the sample axis. Since V is now equivalent to the third laboratory axis, W , it can be shown that for all transitions f , $K'_f = (1 - K_f)/2$. We obtain

$$\begin{aligned} E_U(v) &= \sum K_f A_f(v) \\ E_V(v) &= \frac{1}{2} \sum (1 - K_f) A_f(v) \\ LD(v) &= \frac{1}{2} \sum (3K_f - 1) A_f(v) \end{aligned} \quad [9]$$

When the two curves $E_U(v)$ and $E_V(v)$ differ very little, that is when the $LD(v)$ is small, a direct measurement of $LD(v)$ by means of polarization modulation provides a more accurate result. The second (linearly independent) curve is then either the isotropic spectrum

$$\begin{aligned} E_{\text{iso}}(v) &= [E_U(v) + 2E_V(v)]/3, \\ E_V(v), \text{ or} \\ &[E_U(v) + E_V(v)]/2 \end{aligned}$$

Many important samples have been shown to be or are assumed to be uniaxial, for example solutes in stretched polyethylene or in nematic liquid crystals. It is now simple to determine K_f . If transition f dominates the absorption at v_f (if it does not overlap with other transitions), the dichroic ratio at v_f , $E_U(v_f)/E_V(v_f)$, can be written

$$\frac{E_U(v_f)}{E_V(v_f)} = \frac{2K_f}{1 - K_f} \quad [10]$$

Therefore, K_f can be directly determined:

$$K_f = \frac{E_z(v_f)}{2E_V(v_f) + E_U(v_f)} \quad [11]$$

The situation for nonoverlapping transitions is common in IR spectroscopy, but less common in UV spectroscopy. If transition f is overlapped by other transitions, it is still often possible to determine K_f . This is done by a trial-and-error method (the TEM method) in which a

series of linear combinations of the observed spectra are formed, using values of K near the expected value for K_f :

$$\frac{1}{2}(1 - K)E_U(v) + KE_V(v) \quad [12]$$

The spectral feature (peak, shoulder) due to transition f disappears from the linear combination when $K = K_f$. This may provide a very accurate determination of K_f , even in cases of strong overlap. **Figure 1** shows the observed spectra, the dichroic ratio ($E_U(v)/E_V(v)$), and linear combinations of the former that allow a determination of the two different K values present in the

Figure 1 UV spectra of pyrene in stretched polyethylene at 77K. Absorbance in arbitrary units. (a) E_U and E_V (baseline-corrected) and the dichroic ratio E_U/E_V . (b) and (c) Linear combinations of E_U and E_V , in search of spectral curves corresponding to A_z and A_y , respectively (the TEM (trial-and-error) process). spectrum from the disappearance of the three major peaks in the spectrum.

Figure 2 shows a plot of K_z values against K_y values for a large number of symmetrical molecules aligned in stretched polyethylene. Obviously, shape is very important for the alignment. The triangle shows the theoretical limits for the K values, assuming that $K_z \geq K_y \geq K_x$. The lower left side corresponds to a rod-like alignment, $K_x = K_y$, and the lower right side to a disc-like alignment, $K_z = K_y$.

It is remarkable that the simple use of squares of directional cosines (the K values; sometimes equivalent quantities are used, the Saupe S matrices and the order parameters) provides a description of all directional properties of the sample, which can be observed in absorption spectroscopy, without any assumptions. Several alternative descriptions (the Fraser–Beer model, the Tanizaki model, the Popov model) involve assumptions that are rarely fulfilled. At the same time, some of these models tend to be mathematically complex. A simple extension of the K values to averages of fourth powers of

directional cosines (L values) makes it possible to describe two-photon processes (luminescence, two-photon absorption, Raman) in aligned samples.

Linear Dichroism Spectra: Interpretation

Photoselection

We shall in the following only consider the photoselection of a subset of molecules from an isotropic, 'stationary' sample. By stationary is meant that the sample molecules do not rotate on the timescale of the experiment. Descriptions of photoselection from an already aligned sample or, from a sample with molecular rotational movement, or of photoselection of each molecule with two photons, are more complicated but are available in the literature. Photoselection is usually performed with a collimated light beam with a well-defined wavelength; the light may be either linearly polarized or natural/circularly polarized, the two latter will produce similar results.

Figure 2 Values of (K_z , K_y) for aromatic molecules in stretched polyethylene at 293 K. The molecular z axes are horizontal in the structures, the y -axes are vertical. Adapted by permission from Thulstrup EW and Michl J (1982) *Journal of the American Chemical Society* 104: 5594–5604.

When an aligned subset of sample molecules is selected, another aligned subset, that consisting of the remaining molecules, is also created. When the sample depletion is negligible, the former set of molecules is small in number, but have a high degree of alignment, while the remaining molecules have negligible alignment. When the sample depletion is substantial, both the selected set and remaining set of molecules will be aligned. We shall in the following assume that only one transition is responsible for the photoselection of a small fraction of the sample. Other cases are also of interest and are described in the literature.

Photoselection: Negligible Depletion; Linearly Polarized Light

The photoselected sample becomes uniaxial with respect to the electric vector of the light, which we label U . On the molecular level, the transition moment direction for the transition responsible for the photoselection becomes the orientation axis, which we label molecular axis z . All directions perpendicular to z will have the same K value. We obtain a rod-like alignment of the photoselected molecules: $K_z = 3/5$; $K_y = K_x = 1/5$.

Photoselection: Negligible Depletion; Natural or Circularly Polarized Light

The photoselected sample becomes uniaxial with respect to the direction of light propagation, which we label U . On the molecular level, the transition moment of the absorbing transitions now defines the axis that is least aligned with U , which we label x . We obtain a disc-like alignment of the photoselected molecules: $K_x = 1/5$; $K_y = K_z = 2/5$.

An interesting aspect of these orientation distributions obtained by photoselection is that not only the K values needed for interpretation of absorption spectra but the complete orientation distribution function is known, including the L values.

Anisotropic (Uniaxial) Solvents

In the case of molecules aligned in stretched polymer sheets or nematic liquid crystals, the orientation distribution is unknown. Nevertheless, K values for many or all relevant transitions may be easily determined using the TEM method. For molecules with only two different K values, for example with a C_3 or higher axis, and in spectral regions where only two different K values exist, linear combinations of the two observed spectra may be formed that correspond to sums of contributions from transitions with the same K value.

One important example is that of π - π^* transitions in a molecule of C_{2v} or D_{2b} symmetry. The transition moments for these are restricted to two different, perpendicular directions in the molecule; we shall label

these directions y and z . The sum of contributions from z -polarized transitions is

$$A_z(v) = [(1 - K_y)E_U(v) - 2K_y E_V(v)] / (K_z - K_y)$$

while the sum of contributions from y -polarized transitions is

$$A_y(v) = [2K_z E_V(v) - (1 - K_z)E_U(v)] / (K_z - K_y)$$

Figure 3 illustrates the resulting curves for the π - π^* transitions in pyrene. The separation of transitions into two groups may help identify excited-state symmetries, separate close-lying, differently polarized transitions and reveal hidden transitions. It thereby simplifies the assignment of both electronic and vibrational transitions considerably.

If the molecule is of lower symmetry, very useful, but less specific, results can still be obtained. Let us assume that the molecule has a symmetry plane as its only symmetry element and that the out-of-plane direction, x , corresponds to the lowest possible K value, K_x . Transitions must be polarized either along x or in the yz plane, perpendicular to x . We may therefore observe the following K values: $K = K_x$ or $K_y \leq K \leq K_z$.

For a transition f in the (y, z) plane, the angle between the molecular long axis, z , and the transition moment M_{0f} for transition f , (z, M_{0f}) , can now be determined from K_y , K_z and K_f :

$$\tan^2(z, M_{0f}) = \frac{K_z - K_f}{K_f - K_y} \quad [13]$$

An example of the determination of such angles in a molecule with only the molecular plane as symmetry element is shown in **Figure 4**.

Macromolecules, especially DNA, that are difficult to dissolve in stretched polymer sheets or nematic liquid crystals have often successfully been aligned in a flow.

Figure 3 Curves corresponding to purely z -polarized (A_z) and purely y -polarized absorbance (A_y) obtained by the TEM method. Adapted by permission from Michl J and Thulstrup EW (1995) *Spectroscopy with Polarized Light: Solute Alignment by Photoselection, in Liquid, Polymers, and Membranes*. New York: Wiley-VCH.

Figure 4 UV spectra of dibenz[*a,h*]anthracene. An example of a planar molecule for which π - π^* transition moments may be along any direction in the molecular plane. The curves are linear combinations of E_U and E_V and correspond to transitions that form angles of 0°, 15°, 30°, 45°, 60°, 75°, and 90° with the molecular *z* axis. Adapted by permission from Pedersen PB, Thulstrup EW, and Michl J (1981) *Chemical Physics* 60: 187–198.

Figure 5 UV absorption (E_{iso}) (a) and LD spectra (b) of two derivatives of benz[*a*]pyrene, covalently bound to DNA aligned in a flow. Both derivatives are dihydroxyepoxytetrahydrobenzopyrenes, but their two hydroxy groups are positioned on different sides of the molecular plane (*syn*, broken line; *anti*, full line). The absorption below 300 nm is mainly due to the DNA bases, the planes of which are predominantly perpendicular to the DNA helix axis. This explains the negative linear dichroism below 300 nm. The absorption above 300 nm is mainly due to the two derivatives; it is seen that *anti* has a positive LD, corresponding to a small angle between its molecular plane and the helix axis, while *syn* has a negative LD, corresponding to a large angle between its molecular plane and the helix axis. The biological difference between the two molecules is considerable; *syn* is a weak carcinogen, while *anti* is a very strong one. Adapted by permission from Tjernerl F (1982) Thesis, Chalmers University of Technology, Gothenburg, Sweden.

Flow LD is measured in a solution between a stationary and a fast-rotating cylinder using a Couette or Maxwell cell. It has proved very useful for the study of the interaction between macromolecules and smaller molecules, for example the attachment of carcinogenics to DNA. The long axis of the DNA molecules, the helix axis, becomes the orientation axis. So far such studies have primarily been performed in the UV-visible region. The two linearly independent spectra obtained are

$$\begin{aligned} LD(v) &= E_U(v) - E_V(v) \quad \text{and} \\ E_{iso}(v) &= [E_U(v) + 2E_V(v)]/3 \end{aligned} \quad [14]$$

The latter curve may be obtained when the flow is stopped. **Figure 5** shows $E_{iso}(v)$ and $LD(v)$ for two metabolites of benzo[*a*]pyrene, of which one is a strong carcinogen, the other weak. The measurement was done in a Couette cell containing a mixture of a small amount of a metabolite with DNA in a weak solution of sodium cacodylate in water. The strong absorption of the DNA bases dominates the spectrum below 300 nm (with a negative LD because the DNA base absorption is polarized in the molecular planes of the bases, which are almost perpendicular to the helix axis).

The weak LD absorption of the metabolites correspond to an in-plane polarized transition; it can be studied above 300 nm. The stronger carcinogen of the metabolites has a positive LD, the other a negative. This means that the former is positioned with its molecular plane relatively parallel to the helix axis, while the molecular plane of the latter is more perpendicular to the helix axis.

Symbols

E_{iso}	absorbance in an isotropic sample
E_U	absorbance with the electric field vector parallel to the unique axis, U
E_V	absorbance with the electric field vector perpendicular to the unique axis (parallel to the perpendicular axis, V)
U	the unique optical axis
ω	angle complementary to the incidence angle in the 'tilted plate method'

All linear dichroism (LD) measurements are performed on anisotropic samples. Many samples occurring in nature are partially oriented from the start. Nevertheless, most LD experiments are performed on samples that have been aligned in the laboratory. Therefore, prior to learning the techniques of measurement, one should become familiar with different procedures used to align molecular ensembles.

Methods of Alignment

The majority of LD studies are done on partially aligned samples, which exhibit uniaxial orientation. Such samples have a unique direction (optical axis, unique sample axis) with respect to which the solute molecules are oriented. All directions perpendicular to this axis are equivalent. The most widespread method for obtaining partial alignment is the use of anisotropic solvents: stretched polymers or liquid crystals.

Stretched Polymers

This is the simplest and the least expensive method. Solute may be introduced into the polymers by (i) swelling the polymer with a solution containing the substrate; (ii) diffusion of the vapour of the substrate into the polymer; (iii) casting a film of the polymer from a solution containing the substrate; or (iv) dissolving the substrate in a molten polymer. The most commonly used polymers are low-density polyethylene, best for nonpolar solutes, and polyvinyl alcohol, used for polar and nonpolar solutes. Both are transparent in the UV-visible regions, and in some regions

of the infrared. Mechanical stretching produces uniaxial orientation, its degree increasing with the stretching ratio. The mechanism of orientation is still under debate, but it is evident that the molecular shape is an important factor: the more elongated molecules align on the average better than those that have more spherical shape.

Liquid Crystals

These are experimentally more demanding than polymers. Usually, thermotropic liquid crystals are used, either nematic or compensated nematic mixtures, obtained from cholesteric components. Many liquid crystals absorb in the UV, but some are transparent down to approximately 200 nm. The alignment of the liquid crystal sample can be controlled by external electric or magnetic fields, or by cell surface pretreatment such as rubbing or coating. These procedures make it possible to switch the direction of the unique axis from perpendicular to the surface (homeotropic alignment) to parallel (homogeneous alignment). The degree of orientation of the solute depends on its nature and concentration, as well as on the nature and temperature of the sample and the imperfections of the cell surface.

Lyotropic liquid crystals, Langmuir-Blodgett films and even monolayers adsorbed on surfaces can also be used as uniaxial orienting media.

Single Crystals

In principle, this classical technique makes it possible to obtain nearly perfect orientation and absolute polarization assignments. However, both the measurement and the interpretation are often difficult. Very thin crystals are required for electronic absorption studies. Intermolecular interactions (Davydov splitting) often complicate the spectra. The solution is to find a single crystal of a suitable host molecule, transparent in the region of interest. These two conditions are often very difficult to meet simultaneously.

Electric and Magnetic Fields

Linear dichroism produced as a result of applying an electric field is known as electric dichroism (Kerr effect). The effect is usually quite small for normal-sized molecules, although polymers such as DNA can be oriented very well. The orientation imposed by a magnetic field is

even smaller, and therefore its practical use is limited to large molecular ensembles (Cotton–Mouton effect).

Flow Field

Macromolecules, such as DNA, can become orientated by the hydrodynamic shear associated with liquid flow. This is realized experimentally in a Maxwell cell (sometimes referred to as Couette cell). The cell consists of a fixed cylinder and a rotating cylinder: a flow gradient is produced in the liquid solution contained in the annular gap between the two cylinders.

Photoselection and Photoorientation

This elegant method allows one to obtain a set of partially oriented molecules in a completely isotropic medium. It makes use of the fact that the photoexcited ensemble of molecules is always anisotropic, and thus exhibits LD (transient dichroism). Moreover, if the excitation is followed by chemical transformation, and the environment is rigid enough to prevent molecular rotation, a permanent alignment of both reactant and product is obtained. Such photooriented samples can be studied by conventional LD techniques. Particularly attractive media for use in photoorientation are low-temperature rare gas matrices, which are inert and transparent in both the UV-visible and the IR regions.

Techniques of Measurement

For partially oriented uniaxial samples, two linearly independent spectra can be obtained from an experiment, irrespective of the mode of measurement and the polarization state of the absorbed light. The obvious procedure is to record two absorption spectra, one with the electric vector of light parallel to U , the unique axis of the sample (E_U), the other with the electric vector perpendicular to the unique axis (E_V). The spectra must be baseline-corrected by subtracting the curves recorded on pure solvents. This yields the largest difference between the two linearly independent spectra. Other alternatives

are also possible. A combination of E_U or E_V with the spectrum of an isotropic sample, E_{iso} ($= [E_U + 2E_V]/3$) is easily obtained in liquid crystal. In cases where the sample geometry precludes the measurement of both E_U and the isotropic spectrum (e.g. in membranes), the two spectra are E_V and E_ω , the latter recorded with the incidence angle $\pi/2 - \omega$, and with the plane of polarization containing the U axis (the ‘tilted plate method’). Another possibility is to combine either E_U or E_V with the unpolarized spectrum measured with a depolarizer in front of the sample and the light beam perpendicular to the U axis. Finally, one can use procedures that do not require the use of a polarizer at all, such as recording first the E_V spectrum for an aligned liquid solution (with light propagating along the U axis), and then E_{iso} for the same solution with temperature raised above the isotropic melting point.

All these measurements can be performed on a commercial double-beam spectrophotometer (i.e. singular) supplemented with one or two linear polarizers (Figure 1). Calcite Glan prisms are used for measurements down to approximately 220 nm. Sheet polarizers can tolerate larger apertures and are much cheaper. On the other hand, their transmission is lower and the wavelength range usually limited to the visible range, although the UV-transmitting polarizing sheets have become available.

Various potential sources of errors in LD measurements are (i) scattering and depolarization by the sample, particularly significant in the UV region; (ii) sample inhomogeneity and irreproducibility, which often makes it difficult to reliably record the baseline; (iii) sample birefringence; and (iv) polarization bias of the instrument. For weakly dichroic samples, the separate recording of two spectra is not practical, and the LD has to be measured directly. This is achieved by modulation methods. The state of polarization of the light beam is modulated in time, using a combination of a linear polarizer and, most often, a photoelastic modulator. Since the transmission of the dichroic sample varies for different polarizations of the light, the detector produces an a.c. signal, superimposed on the d.c. signal, owing to the

average intensity of the transmitted beam. The analysis of the two signals allows an evaluation of the LD and of the average optical density of the sample. For measurements of this type, one can adapt a spectropolarimeter normally used for circular dichroism measurements (**Figure 2**).

Although most LD studies are performed by recording the intensity of transmitted light, other methods are also used. One of them detects the LD via fluorescence, and another uses photoacoustic spectroscopy. Both methods are very sensitive and avoid some of the errors inherent in the transition mode, such as light scattering.

Most of the alignment techniques and methods of measurements used for electronic linear dichroism can be adapted for studies in the IR region. The merits of IR-LD make this technique a very attractive choice, complementing and in many respects surpassing the information content provided by electronic linear dichroism.

Since the first publications on this subject in 1963, NMR in liquid crystalline systems has been a wide and active field of research in many branches of organic and physical chemistry. In fact, NMR spectroscopy has revealed a powerful means of probing molecular structure, anisotropic magnetic parameters and dynamic behaviour of solute molecules dissolved in liquid crystals. Moreover, this technique has been successfully employed to investigate properties of mesophases themselves, such as their orientational ordering, translational and rotational diffusion and their effects on nuclear relaxation, and molecular organization in different liquid crystalline phases.

NMR of different nuclei has been performed: ^1H , ^2H and ^{13}C NMR have been used extensively, but a number of studies are reported on ^{14}N , ^{19}F , ^{23}Na and ^{31}P also. NMR of active isotopes of noble gases dissolved in liquid crystals has also been employed.

Liquid Crystals

We define a liquid crystal as a state of aggregation that is intermediate between the crystalline solid and the amorphous liquid. In this state the molecules show some degree of orientational order with respect to a preferred direction, n , called the director; long-range positional order does not exist or is limited to one or two dimensions.

In several liquid crystal phases, termed uniaxial phases, only one director is required to describe the molecular order. In contrast, for biaxial phases the orientational order needs two directors for its description. The principal molecular axes are uniformly aligned only on average. The degree to which the molecules are ordered about the director is described by means of a number of parameters, called order parameters.

Substances that show a liquid crystalline phase, or mesophase, are called mesogens. Several thousands of compounds, both with low molecular mass and polymeric, are now known to form mesophases. They are mainly highly geometrically anisotropic in shape, rodlike or dislike (hence the terms calamitic and discotic liquid crystals), or they are anisotropic in solubility properties, like amphiphilic molecules and, depending on their detailed molecular structure, they can exhibit one or more mesophases between the crystalline solid and the isotropic liquid. Transitions to these intermediate states may be induced by purely thermal processes (thermotropic liquid crystals) or by the action of solvents (lyotropic liquid crystals). Each of these two categories can be further divided according to the structure of the mesophases and/or molecules; **Scheme 1** shows the classification of thermotropic mesophases.

Macroscopic Alignment

When subjected to an external magnetic field B_0 of sufficient magnitude ($> 0.5\text{ T}$), the molecules in a mesophase exhibit a macroscopic orientation so that the director n is uniformly aligned in the whole sample. The magnetic field exerts a torque on the molecules, which reorientate cooperatively; the induced reduction in free energy is $\Delta G = \Delta\chi B_0^2 (3\cos^2\alpha - 1)/6$, where $\Delta\chi = \chi_{\parallel} - \chi_{\perp}$ is the difference between the component of the diamagnetic bulk susceptibility along ($\chi_{\parallel}$) and perpendicular to ($\chi_{\perp}$) the director and α is the angle between the director and the magnetic field. The direction of minimal G , that is the preferred orientation of n depends on the sign of $\Delta\chi$. Thus, for calamitic mesogens with aromatic cores, which have $\Delta\chi > 0$, n aligns parallel to B_0 , while for those formed uniquely by aliphatic units $\Delta\chi < 0$ and n aligns perpendicularly to B_0 . Most discotic liquid crystals have $\Delta\chi < 0$, and thus an orientation of n perpendicular to B_0 is observed.

The response time for the alignment depends on the relative values of the magnetic torque experienced by the molecules and of the opposing viscous torque. For most

Scheme 1 Classification of thermotropic liquid crystals.

nematic liquid crystals it takes only a few seconds; for some lyotropic phases the alignment is relatively slow and takes minutes or hours. Smectic and columnar discotic liquid crystals are sometimes very viscous and a uniform alignment can only be obtained by reaching these mesophases on slow cooling from the nematic or isotropic phases. For cholesteric samples, the presence of magnetic fields can untwist the helical structure, giving rise to a nematic phase.

Molecules dissolved in liquid crystal solvents become partially oriented, the degree of orientation being dependent on the nature and concentration of the solute.

Observable Interactions

The NMR spectra of molecules in a liquid crystalline environment, either mesogenic molecules or solutes, are dominated by second-rank tensorial properties (**T**) such as the shielding tensor (σ_i), the dipolar and indirect spin–spin interactions ($\mathbf{D}_{ij}$ and $\mathbf{J}_{ij}$) and, for nuclei with $I > 1/2$, the quadrupolar interaction ($\mathbf{q}_i$). In most liquid crystals, molecular reorientations and internal motions reduce these interactions to a well-defined average, without the loss of all information. Moreover, molecular translational diffusion averages out to zero the intermolecular interactions, which thus do not complicate the partially averaged spectra. In the usual high-field approximation, in NMR experiments we measure T_{zz} , the component of the averaged interaction tensors resolved along the magnetic field direction (z in the laboratory frame).

The observed averaged quantities are related to the interactions in their principal axis systems (PAS), fixed on the molecules or on rigid molecular fragments, by several transformations of reference frames. Since the molecules are not fixed in a lattice, another frame, the liquid crystal (director) frame (LC), has to be defined. The transformation between the molecular and the LC frame is time dependent because of molecular reorientational motions and the use of the order parameters is needed in this step.

Thus T_{zz} relates the NMR measured quantity to the molecular ordering in the mesophases by a number of order parameters depending on the symmetry of the molecule and phase. Measurements of partially averaged second-rank tensors give access only to second-rank order parameters, which are equal to 0 for completely disordered systems, and range from -0.5 to 1 for partially ordered systems, according to $\langle 3l_\alpha l_\beta - 1 \rangle / 2$, where l_α and l_β are the direction cosines between the PAS and the LC frames. The last step, from the LC frame to the laboratory frame, requires integration over all possible orientations in the case of a powder sample, or the use of a distribution around some preferred orientation in the case of an aligned sample.

Chemical Shift Anisotropy

NMR spectroscopy of oriented molecules provides a simple method for measuring chemical shift anisotropies, $\Delta\sigma_i$. The change in chemical shift with respect to a reference signal as a function of the molecular degree of order, which can be varied by changing phase and temperature, determines the elements of the shift tensor. In practice, however, the direct measurement of $\Delta\sigma_i$ poses problems related to the reference signal, which depends on changes in local and bulk effects produced by variable sample temperature, phase transitions and degree of alignment with temperature. The variable angle spinning (VAS) method can be used to avoid some of these problems.

Dipolar and Indirect Couplings

The direct dipolar coupling, D_{ijzz} , and J_{ij}^{aniso} , the anisotropic component of the indirect spin–spin interaction in the direction of the magnetic field, appear in the Hamiltonian in the same form. The splittings that arise in NMR spectra are the sum of these two quantities, called the experimental anisotropic coupling ($T_{ij} = 2D_{ijzz} + J_{ij}^{\text{aniso}}$). It is therefore important to know

Table 1 Quadrupolar coupling constants for deuterium

C–D bond hybridization	Quadrupolar coupling constant (kHz)
sp	200 ± 5
sp ²	185 ± 5
sp ³	170 ± 5

experimentally, or to evaluate theoretically, the values of the pseudo-dipolar coupling J_{ij}^{aniso} in order to accurately determine D_{ijzz} , which is related to the order parameter of the direction joining the two nuclei and to their distance, that is to molecular structure. On the other hand, the magnitude of J_{ij}^{aniso} , and in particular the components of J_{ij} expressed in a molecular axis system, is related to the molecular electronic structure. The measurement of a finite value of J_{ij}^{aniso} is not an unambiguous process, as it does not have a unique effect on the spectrum. Attempts to obtain values of J_{ij}^{aniso} for different pairs of nuclei have been made, and it has been concluded that some indirect couplings such as ^1H – ^1H , ^1H – ^{13}C , and ^{15}N – ^1H have small anisotropic contributions, while other couplings such as ^{13}C – ^{13}C , ^{19}F – ^{19}F , ^1H – ^{19}F and ^1H –X (where X is Hg, Cd, Si and Sn) may have a significant contribution from the anisotropic term.

Quadrupolar Interaction

Nuclei with spin $I > 1/2$ possess electric quadrupole moments which, in the presence of an electric field gradient, give an additional contribution to the spin Hamiltonian, termed the quadrupolar interaction. In anisotropic media this interaction produces line broadening and gives rise to additional lines in the spectrum. ^2H has a relatively small quadrupolar moment and is therefore particularly useful for studying anisotropic media. In an X–D bond the field gradients arise almost entirely from the charge on X, and it can be usually assumed that the X–D bond lies parallel to the principal axis for $\mathbf{q}_b$, the quadrupolar interaction tensor. Furthermore, for C–D bonds the quadrupolar coupling constants are found to have typical values depending on hybridization (see Table 1).

NMR of Liquid Crystalline Solutions

Structural Studies of Rigid Molecules

^1H NMR spectroscopy in oriented media has been widely employed for determining the structure of rigid molecules. Proton spectra in nematic solvents are dominated by homonuclear dipolar couplings, D_{ijzz} , whose magnitudes are large (up to 3–5 kHz) compared to the line width and the chemical shift differences and which are observable between all active nuclei in a molecule. The spectra can be very complex (see Figure 1) even for

Figure 1 300 MHz proton spectrum of a sample of biphenyl dissolved in the nematic solvent ZLI1115.

molecules with a small number of nuclei and various strategies have been devised for their analysis.

For simple spin systems, analytical solutions to the Hamiltonian can be found and transition frequencies and intensities can be written in closed forms. Spectra of complex systems may be simplified by reducing the number of nuclei contributing to them. This may be achieved by partial deuteration of molecules followed either by spin decoupling or by spin-echo refocusing. Alternatively, simplified spectra may be obtained by VAS or multiple-quantum experiments. Complex spectra have been analysed by iterative and automatic methods using computer programs; both require good starting parameters, which can be obtained from simplified spectra, and an experienced operator.

Methods for automatic analysis have been improved allowing the treatment of very complex systems; with these procedures it is possible to analyse spectra that depend on up to 27 spectral parameters.

The dipolar couplings obtained from spectral analysis are then used to determine molecular geometries, namely bond lengths and angles. Since these couplings depend on both geometrical factors and order parameters, they never define an absolute length but only relative distances. In contrast, angles can be measured absolutely.

Only for very simple molecular systems with favourable symmetry are there enough dipolar couplings for the determination of both the structural and the order parameters. In more complex cases, the solution must be found iteratively by computer calculations, and appropriate programs, such as SHAPE, have been written for this purpose. To get a unique and precise geometrical solution in the case of complex systems, it is highly recommended to record several spectra of the same molecule in different solvents. In addition, information on the carbon positions may be derived from the dipolar coupling constants D (^{13}C –H)

observed as the ^{13}C satellites in the proton spectra, even though this method has two considerable disadvantages: the spectra are quite complex and the measured ^{13}C -H couplings are usually less precise than H-H couplings.

The presence of molecular vibrations makes internuclear distances and angles, and therefore the degree of ordering, time dependent. Thus the NMR structural data must be corrected for vibration. The harmonic correction can be computed relatively easily and a computer program, VIBR, is available; the structure corrected for these effects, called the r_z structure, has the advantage of being unaffected by shrinkage effects, and can be compared with the data obtained from different spectroscopies.

The determination of molecular structure by ^1H NMR spectroscopy in oriented media is apparently extremely precise: dipolar couplings of the order of 10^3 Hz can be measured with an error of 10^{-1} Hz, thus giving a precision of 10^{-5} in distance ratios. In practice, however, limitations to structure precision apply because of solvent effects, vibrational corrections and anisotropy of the indirect coupling constants, and the precision that can be easily reached is of the order of 10^{-2} Å in bond lengths and 10^{-1} degrees in angles. As far as solvent effects on the structure are concerned, correlations of molecular shape with angular orientation have been observed. For example, they are responsible for the observation of dipolar and quadrupolar splittings in NMR spectra of molecules that in their equilibrium conformation possess tetrahedral and higher symmetry. The use of 'magic' mixtures has been suggested in order to obtain minimal distortions. Theoretical evaluations of the deformations have been made and used to correct the NMR couplings in structural studies.

^2H NMR has been used to determine quadrupolar coupling constants and asymmetry parameters, once the molecular structure and orientational order parameters are known.

NMR in nematic solutions has also been applied in the study of weak molecular complexes. The interactions of systems such as pyridine, pyrimidine and quinoline with iodine have been investigated. ^1H and ^{13}C NMR spectra have been recorded and analysed in order to detect whether the complex formation measurably affects the molecular structure, that is the proton and carbon positions. Since these effects are small, vibrational as well as deformation corrections have been performed.

Structural Studies of Flexible Molecules

The presence of large, low-frequency intramolecular motions (such as internal rotation and ring puckering) considerably complicates the interpretation of proton NMR spectra of flexible molecules in nematic solvents. In fact, in this case the effects of two simultaneous motional averagings on the magnetic interactions are present: the

internal molecular motions and the overall motions of molecules in the mean potential due to the anisotropic environment. Moreover, owing to possible correlation between these motions, it is not possible to reach the same degree of precision on the orientational and geometrical parameters as can be obtained for rigid molecules.

Information about structure and orientational ordering can be obtained for individual rigid molecular fragments. Problems arise about the relationship between the data relating to different fragments and the interpretation of inter-fragment couplings. In early studies, several approximations were made, case by case, and their degree of soundness was tested by comparison of the results with those from other techniques. Later, systematic approaches were introduced for the analysis of dipolar data from flexible molecules; among which the additive potential (AP) method and the maximum entropy (ME) method have been found to be particularly useful.

Chiral Recognition

A simple and convenient method for enantiomeric analysis by means of NMR has been proposed that consists of using a chiral lyotropic liquid crystal obtained by mixing poly(γ -benzyl-L-glutamate) (PBLG) and various organic solvents. (*R*) and (*S*) enantiomers interact with the chiral centres of PBLG and thus orient differently in the liquid crystal solvent, which implies that all the order-dependent NMR interactions are different for the two enantiomers. ^2H NMR has been applied successfully to a large number of partially deuterated chiral molecules bearing various functional groups: enantiomeric excess (ee) up to 98% has been measured by signal integration. In many cases, chemical shift anisotropy of ^{13}C in natural abundance may be used to discriminate enantiomers and to measure ee through conventional integration with an accuracy of about 5%. In this case, isotopic enrichment is not needed and more sites in the same molecule may be observed in the same spectrum. On the other hand, chemical shift differences between enantiomers can be very small (a few hertz) and, in particular for hydrocarbons, the method may not work. Also, the chiral recognition mechanism in PBLG is not fully understood so that it is not possible to assign absolute configurations.

Probe Studies of Liquid Crystals

A well-developed approach to the study of structure and dynamics of liquid crystals is based on the use of probes, although the probe can disturb the mesophase. Generally, highly symmetric and rigid molecules are dissolved in mesophases, but, for special purposes, different probes can be chosen; for instance, for lyotropic systems the solvent itself can be used as a probe of the behaviour of aggregates.

The order and dynamic behaviour of probes, revealed by suitable NMR techniques, have been used to study phase transitions and pretransitional phenomena. They are also useful for revealing segregation effects: when highly ordered smectic or columnar discotic phases organize themselves, they may exclude added solutes or confine them in aliphatic or interlayer regions.

The anisotropic potential acting on a probe is a solute–solvent property and therefore the study of probes gives valuable insight into the mechanism governing solute–solvent interactions. It has been found that very often the probe and the solvent can interact more or less specifically and in some cases an exchange between two or more sites has been inferred from large effects on the apparent geometry of the dissolved molecule.

Noble gases have been used as probes and have proved to be very useful for obtaining information about physical properties of liquid crystals. In particular, the shielding of ^{129}Xe is highly responsive to the structure and temperature of the environment and ^{129}Xe NMR has been employed to monitor phase transitions of thermotropic and lyotropic liquid crystals and the formation of induced smectic phases. Quadrupolar noble gas nuclei are powerful probes for detecting electric field gradients (EFG); ^{131}Xe , ^{83}Kr and ^{21}Ne quadrupolar splittings and relaxation behaviour in various calamitic liquid crystals have given hints that there are two contributions to the EFG at the site of the nucleus: one is attributed to the distortion of the electron cloud of the atom from spherical symmetry and the other is the external EFG produced by the electric moments of the neighbouring molecules.

Oriented Bicelles as a Medium for Macromolecular Structural Studies

Bicelles are a membrane mimetic system with a planar surface and a mixed phospholipid composition; they have magnetic field orientation and morphological properties that make them amenable to both solid- and solution-state NMR spectroscopy.

These “binary bilayered mixed micelles” or bicelles have been used extensively in the last few years as an alignment medium for proteins in solution with the aim of measuring residual dipolar couplings and chemical shift anisotropies and these parameters provide a measure of the angle that bonds make with the magnetic field, and thus by suitable calculation lead to the build-up of structural and relative orientational information between atoms in a protein. This idea was first introduced by Bax and co-workers in 1997 who used diluted solutions of aligned bicelles with a volume fraction of ca. 5% to measure the residual ^{15}N – ^1H dipolar interactions in labelled proteins and thus to obtain additional information for protein structure determination. The use of such

residual dipolar couplings in the study of protein structure has been reviewed by Bax (see Further Reading).

Isotropic bicelles can also be used for the structure determination of membrane-associated proteins by solution-state NMR spectroscopy. In addition, oriented bicelles provide information on protein interactions and conformations by using solid-state NMR techniques. The addition of lanthanide ions can flip the bicelle orientation in the magnetic field and allows further investigation of the interaction and structure of membrane-bound proteins. Slowly spinning bicelle preparations at various angles relative to the orienting magnetic field can also be useful to obtain structural information on membrane-associated peptides.

NMR of Liquid Crystals

Study of Orientational Order

Long-range orientational order is a fundamental character of liquid crystals. NMR is perhaps the most powerful technique for studying this property at the molecular level; its results are extremely useful for testing molecular theories that predict the variation of orientational order as a function of temperature, especially in uniaxial mesophases. The order parameters of different molecular segments in a liquid crystal can be obtained from ^2H quadrupolar couplings, ^2H – ^2H , ^2H – ^1H and ^{13}C – ^1H dipolar couplings, ^{13}C chemical shifts and, for fluorinated mesogens, from ^{13}C – ^{19}F dipolar couplings and ^{19}F chemical shifts.

The study of deuterium interactions is now a general method in liquid crystal research and, although it requires use of specially deuteriated compounds, it has been widely applied to both thermotropic and lyotropic mesogens. ^2H NMR spectra of aligned samples are well resolved and relatively simple (see Figure 2). An analysis of these spectra allows the magnitude of quadrupolar and, in some cases, dipolar splittings to be obtained, which are related to local order parameters for the ^{13}C – ^2H , ^2H – ^2H and ^2H – ^1H directions.

^{13}C – ^1H dipolar couplings of a large number of calamitic liquid crystals have been determined by SLF/VAS, a 2D ^{13}C NMR technique which combines separated local field spectroscopy (SLF) and variable angle spinning (VAS). In this method, mesogens with ^{13}C in natural abundance are used; however, special software and hardware as well as prolonged spectrometer time are required. It has been shown that the order parameters of the phenyl rings and the aliphatic C–H bonds in liquid crystals, determined by the SLF/VAS technique, are linearly related to their ^{13}C chemical shifts. The same linear correlation is applicable to different compounds in a homologous series: this provides a convenient means for the determination of the order parameters of liquid crystals from their ^{13}C

Figure 2 30.7 MHz ^2H NMR spectrum of 5CB- d_{15} . The peaks are labelled according to their assignment to sites in the molecule. Reproduced with kind permission from Kluwer Academic Publishers from Emsley JW (1985) In: Emsley JW (ed.) *NMR of Liquid Crystals*, p. 397. Dordrecht: Reidel.

chemical shift data, without the need to know the chemical shift tensors.

The local order parameters obtained by the various methods can be used to describe the orientational ordering of molecules, or fragments of molecules, through reference system transformations that require assumptions about geometry (i.e. bond length and angles) and conformational distributions. Usually, the order parameters for the aromatic core of mesogens can be determined quite accurately and can be assumed as a measure of the molecular ordering in the mesophases: values up to 0.6–0.7 are found for nematic phases, while values up to 0.9–1.0 are typical of highly ordered smectic and columnar discotic phases.

In fortunate cases the measured interactions also allow the calculation of structural parameters of molecular fragments, the structure of mesogenic molecules being too complex for a complete determination.

As far as side chains are concerned, the local order parameters relative to the various CH_2 and CH_3 groups give a measure of chain disorder, being dependent on chain flexibility and conformation–orientation correlations. Different theories of orientational ordering in flexible chains, such as the AP and the chord models, have been formulated and critically tested by comparison with experimental data (see **Figure 3**).

Phase Structure Determination

NMR spectroscopy can provide valuable information on the structure of mesophases. The most commonly used method for this is the analysis of line shapes in spectra of various nuclei, and, in particular, of ^2H . For a large number of mesophases, ^2H NMR spectra are motionally averaged and the spectral line shape reflects the phase symmetry. Line shape analysis of ^2H NMR spectra has been employed successfully to investigate the molecular

Figure 3 (a) Molecular geometry and interacting modules of the 8CB molecule in the chord model; (b) orientational order parameter profile of 8CB at $T_c - T = 4$ K. The open circles represent experimental values; the bold line gives the calculated profile using the chord model, while the fine line gives the calculated profile using the AP model. The order parameter of the cyanobiphenyl para-axis ($i = 0$) is reduced by 50% for plotting convenience. organization and tilt angle of smectic C phases, as well as the structure of columnar discotic phases and it has been shown to be more sensitive than optical techniques to some aspect of biaxial ordering. Moreover, this technique has been shown to be extremely helpful in the discrimination of lyotropic phase symmetry. As examples, ^2H NMR spectra of some lyotropic phases are reported in **Figure 4**.

Other nuclei can be useful in determining structure of lyotropic liquid crystals. In fact, ^{14}N and ^{31}P NMR have been applied successfully to investigation of the structure of phospholipid aggregates in water.

Molecular Dynamics

The complex dynamics of liquid crystals is characterized by a superposition of local and collective motions, comprising internal isomerization, overall rotational diffusion (rotation of the molecule about the long axis and re-orientation of this axis) and translational diffusion, and collective order fluctuations. Different NMR techniques

Figure 4 Schematic view of the cylindrical (a), ribbon (b) and lamellar (c) lyotropic aggregates along with their corresponding ^2H NMR spectral patterns recorded for a potassium palmitate- d_3 in a mixture with 7 wt% potassium laurate and 30 wt% water. are designed to follow these motions and to differentiate the various motional modes on the basis of their timescale.

Overall molecular reorientations and internal motions take place in the 10^{-11} – 10^{-6} s time window and information about them can be accessed using relaxation rate measurements. By far the best approach is to use ^2H NMR experiments where deuterium Zeeman and quadrupolar spin–lattice relaxation times are measured on selectively deuteriated mesogens or on deuteriated probes dissolved in the mesophase. Frequency, orientation and temperature dependence of the spectral densities obtained in these relaxation studies give indications about the various motional modes and are extremely useful for testing orientational diffusion and chain dynamics models. Different deuterium relaxation experiments can be employed to extend the observable dynamic range: the quadrupolar echo sequence gives spin–spin relaxation times sensitive to motions in the range 10^{-8} – 10^{-4} s, while extremely slow motions (10^{-4} – 10 s) are accessible by the Carr–Purcell–Meiboom–Gill pulse train.

Internal and overall motions that take place on a dynamic scale from 10^{-7} to 10^{-4} s can affect the line shape of ^2H NMR powder spectra. This is often the case for phenyl ring rotations or chain isomerizations in polymeric liquid crystals and for rotational diffusion in discotic mesophases. Line shape analysis allows different types of motions to be discriminated and the relative kinetic parameters to be obtained. Moreover multi-dimensional exchange NMR can be applied to characterize molecular details of dynamical processes when the correlation times range between 10^{-5} and 10^2 s.

Fluctuations in the orientation of the director are better investigated by field cycling experiments that allow frequency-dependent T_1 measurements to be performed over a range from 100 Hz to 10 MHz. ^1H and ^2H spin relaxation studies have been carried out for numerous

nematic and smectic liquid crystals to investigate the frequency dependence of director fluctuations, not accessible by experiments run on standard NMR spectrometers. It has been found that this motion is clearly observable by the relaxation rates only at low frequencies, that is below the MHz regime.

The translational diffusion motion is usually monitored on macroscopically aligned samples, by imposing a concentration or field gradient. The range of accessible diffusion rates is determined by the spectral or temporal resolution of the measuring technique. Moreover, translational diffusion constants may be determined indirectly by measuring spin–lattice relaxation times (T_1 , T_{1D} , $T_{1\rho}$) and analysing them in terms of suitable theories.

^1H and ^2H NMR studies of dynamic processes such as isomerization, ring inversion, hindered rotation and intramolecular rearrangement have also been performed on solute molecules in nematic solvents. In the case of proton NMR the dominant anisotropic splittings in the spectra come from the dipole–dipole interaction, and dynamic processes in the range of 10 – 10^3 s $^{-1}$ may be studied by line shape analysis. With ^2H NMR the dominant quadrupolar interaction allows motions in the range of 10^3 – 10^9 s $^{-1}$ to be investigated. Besides the considerably larger dynamic intervals that may be achieved, NMR in liquid crystalline solvents is superior to that in isotropic solvents in revealing the details of reaction mechanisms. In this respect 2D exchange deuterium NMR techniques have also been found helpful.

Introduction

Nuclear magnetic resonance (NMR) is a technique widely used in research, industry, and medicine. Universities and pharmaceutical companies use NMR to determine the chemical and physical structure of molecules whereas magnetic resonance imaging (MRI) is widely used in hospitals for diagnostic purposes. In general, NMR is a technique that suffers from relatively poor signal strength when compared to other spectroscopic or imaging methodologies. However, its great advantages are an ability to measure a variety of molecular properties in a comparatively direct way and the ease with which new experiments can be designed and implemented. Because of these advantages, much effort has gone into improving NMR signal quality. The most straightforward method has been to continually increase the strength of the magnetic field the sample is placed in since, as will be shown, the signal amplitude is strongly dependent on magnetic field strength. Because of this general trend, it is commonly assumed that all new applications will require ever more powerful magnets. However, for a variety of reasons, some of which will be described in this article, there are situations in which lower magnetic fields can be advantageous. Like many new technologies, low-field NMR was, for a while, a technique without any real application. However, this is

no longer the case as the nonexhaustive list of applications in the following text shows. Blumich et al. discuss most of these in detail in their comprehensive review.

- Relaxation time measurements of foodstuffs for quality control.
- Moisture detection, for example, in wood or concrete.
- Oil painting investigations.
- Tire rubber aging.
- Oil well logging.
- Rock core porosity analysis.
- Sea ice porosity.
- Underground water detection.
- Earth's magnetic field monitoring.
- Low-field simultaneous imaging and magnetoencephalography (MEG).
- Field cycling.

NMR Signal Amplitude and Magnetic Field Strength

In this article, the different methods that have been developed to perform low-field NMR will be discussed – in particular, how the problem of poor signal strength has been tackled. This article starts by considering how and why the signal amplitude depends on field strength, since this will identify some of the potential regimes where low-field NMR might be applicable.

The signal strength detected by NMR is determined by several factors; two of the most important are the magnitude of the magnetization produced by the applied magnetic field and the efficiency of the detection process. The first is proportional to the polarizing magnetic field strength B_p , so a larger field will induce a larger magnetization vector (M) that can then be manipulated by the pulse sequence:

$$M = \frac{N_s V (\gamma \hbar)^2 I(I+1) B_p}{3kT} \quad [1]$$

Here N_s is the number of spins per unit volume, V is the sample volume, γ is the gyromagnetic ratio for the nucleus (of spin I) being detected, T is the sample temperature, and k is Boltzmann's constant.

Apart from B_p there are other terms in this expression that can be modified to increase the signal amplitude – the temperature can be reduced, the magnetization can be artificially increased by transferring polarization from

another spin-system with a higher gyromagnetic ratio, and larger volumes V can be used.

Traditionally, the NMR signal is detected using Faraday induction. After being excited by a short radio frequency (RF) pulse, the magnetization is tipped into a plane orthogonal to the polarizing field and then starts to precess about it at the Larmor frequency ($\omega = \gamma B$). This precessing magnetization induces an alternating voltage in a coil wound around the sample (the B_1 coil) – it is this voltage that constitutes the detected signal. This detection method leads to a signal strength that is proportional to the angular frequency ω of the precessing magnetization or equivalently, via the Larmor relationship, proportional to the field strength during detection, B_D . Consequently, the signal will depend on the square of the field strength if the field strength remains constant during the experiment, apparently confirming the assumption made in the first paragraph:

$$S = \omega_0(B_1/I)M \propto B_D B_P \quad [2]$$

Note that the signal strength also depends on the field generating efficiency of the B_1 coil; B_1/I .

Although S is the signal induced into the B_1 coil alone, because it is common to tune and match the NMR probe to 50 ohms the actual measured signal S_M will become:

$$S_M = \omega_0(B_1/I)M \sqrt{\frac{50}{r}} \quad [3]$$

where r is the AC B_1 coil resistance. This depends inversely on the coil quality factor Q and so coils with larger quality factors therefore produce a larger signal.

The noise level is also important when talking about signal quality. The detected noise depends in a complex way on operating frequency, but since the probe is usually tuned and matched to 50 ohms, the noise on resonance will at best be equivalent to that produced by a 50 ohm resistor. Modifying the bandwidth Δf will cause the noise level to vary according to the Johnson noise expression:

$$N_J = \sqrt{4kT\Delta f 50} \quad [4]$$

This is the root mean square (RMS) noise voltage produced by a 50 ohm resistor over a bandwidth Δf at temperature T . Away from resonance, the noise level will vary in a complex way depending on the probe impedance. In addition to reducing the bandwidth, a reduction in coil temperature can lead to reduced noise; however, this will only be significant in the absence of external noise sources. The total noise N_T will always include contributions for external noise sources N_E – which in some applications can dominate. A realistic

measure of signal quality is therefore the signal-to-noise ratio $SNR = S_M/N_T$, where

$$N_T = (N_J^2 + N_E^2)^{\frac{1}{2}} \quad [5]$$

Non-Faraday Detection of Nuclear Magnetization

Although Faraday induction is, because of its simplicity, by far the most common form of detection, there are other techniques that do not scale linearly with frequency. Superconducting quantum interference device (SQUID) detectors, for example, detect the flux due to the nuclear magnetization directly, and so have a sensitivity that is frequency independent. Although not discussed here, other forms of detection such as optical and mechanical are also possible. The relative sensitivity and difficulty of these different methods must be compared to see which is the most appropriate for the operating frequency being used.

Field Homogeneity

Apart from the time domain SNR, the other signal quality factor that is often of importance is the field homogeneity, which determines frequency domain line-width. From a spectroscopy point of view, narrow line-widths mean higher resolution and again the relative (ppm) resolution has tended to improve as field strengths have increased. As is clear from eqn [4], narrower lines typically also imply narrow detection bandwidths that lead to lower thermal noise. One of the questions that is considered in this article is whether one always needs high resolution to perform useful measurements or if it is possible to obtain high resolution spectra without moving to higher-field strengths. There are several reasons for looking at low-field NMR systems with (possibly) poor homogeneity. Perhaps one of the most important is that the price of an NMR spectrometer rises rapidly with field strength and homogeneity, and larger field strengths typically mean bulkier and less mobile magnets. There are also a few applications that even benefit from low-field measurements (e.g., magnetic susceptibility effects get worse as frequency is increased)

To demonstrate the ways in which low-field NMR can be useful, a number of different systems are considered that have avoided the need for high-field strengths or homogeneity or which due to their alternative technology are potentially more useful than conventional systems. To demonstrate the potential of low-field NMR, the following sections will consider systems which have avoided the need for high-field strengths or homogeneity. This discussion starts by looking at NMR systems which are closest in field strength to the traditional superconducting

spectrometer. It then moves down the field scale until the ultimate limit is reached—zero-field NMR.

Permanent Magnet Systems

In this article, low-field NMR will be defined as fields below ~ 1 T. This is a range of field strengths that are quite conveniently produced by permanent magnets. Traditionally, the domain of heavy, water cooled electromagnets, this relatively new technology, provides the advantages of lower cost, weight, and size. NdBFe and SmCo magnets are the two most common materials in use, and magnets in a variety of shapes and sizes are readily available. Much effort has gone into designing magnet configurations that produce relatively large homogeneous regions. For example, the popular Halbach design uses a cylindrical array of magnets to produce a horizontal field inside a vertical bore which can then be conveniently converted into an NMR probe with the addition of a vertically oriented B_1 solenoid and sample. An example is shown in **Figure 1**.

One issue with all permanent magnet-based systems is poor temperature stability. The field produced by permanent magnets drifts between $0.03\% \text{ } ^\circ\text{C}^{-1}$ (SmCo) and $0.1\% \text{ } ^\circ\text{C}^{-1}$ (NdBFe). Insulation and temperature control are therefore required to keep the frequency drift low. This becomes more critical as the field homogeneity is improved. With carefully designed and positioned passive magnetic shims, it is possible to create magnets with < 1 ppm resolution without the use of electrical shims.

Although the addition of electrical shims to permanent magnets is often necessary to provide sufficient resolution to perform spectroscopy and imaging, they do add to the expense and complexity. To this end, a number

of applications have been developed which do not require high spectral resolution.

Time Domain Measurements

For most NMR end users, it is data in the frequency domain that holds the key to unlocking chemical information. This of course requires high resolution in that domain, which implies good magnetic field homogeneity. Although it is possible to design experiments that can partially compensate for poor field homogeneity, there are many complex, naturally occurring materials which have broad, poorly defined spectra. In this case, there are experiments that return useful time domain information and do not require particularly high spectral resolution. Two of these are relaxation and self-diffusion measurements. Because the relationship between these results and chemical and physical structure is rather tenuous, the analysis is often performed using an empirical technique whereby relaxation or diffusion information is matched with results obtained from reference samples. Although simple liquids typically show single exponentially decaying relaxation or diffusion behaviour, more complex materials produce multiexponential data, which can be analyzed using inverse Laplace transform methods to produce *relaxation or diffusion spectra*. This is analogous to the way free induction decays (FIDs) can be decomposed to produce frequency domain spectra by applying the Fourier transform. However, unlike the Fourier transform, the inverse Laplace transform method is ill defined, meaning that for each relaxation curve there can be multiple relaxation spectra, so methods have been developed that produce the most likely spectra – not giving more information than is indicated by the SNR of the data (e.g., see **Figure 2**).

Figure 1 A 2 MHz rock core analyzer based around a temperature-controlled Halbach magnet. (Manufactured by Magritek Ltd). This system measures rock core porosity and because of its low magnetic field (47 mT) has few problems due to susceptibility artifacts.

The core experiment for generating T_2 relaxation data is the CPMG (Carr–Purcell–Meiboom–Gill) pulse sequence. This produces a series of spin-echoes that by refocusing field inhomogeneities is able to correctly sample the T_2 relaxation curve. A problem with performed CPMG experiments in inhomogeneous fields is sensitivity to diffusion effects. If the sample molecules are undergoing significant self-diffusion during the spin-echo time, the echo peaks will suffer unrecoverable attenuation in addition to that expected from T_2 relaxation alone. Because the diffusive attenuation occurs with a time constant that is proportional to the echo time cubed, whereas the T_2 relaxation has a time constant linearly dependent on echo time, it is advantageous to use very short echo times to minimize the diffusive attenuation effect. CPMGs with echo times shorter than 100 μ s are not uncommon.

Because of its sensitivity to diffusion, by performing several CPMG experiments with different echo times, it is possible to extract diffusion information. In the presence of a strong field gradient, it is possible to perform the diffusion measurement in a single experiment – a technique used to advantage with certain one-sided magnets. Relaxation and diffusion pulse sequences can be combined to form 2-D experiments to untangle overlapping relaxation peaks. An example of this is shown in **Figure 3** for a liquid crystal sample in which diffusion is successively encoded along two orthogonal axes to give a correlation pattern that reflects the nature of restricted diffusion in a polydomain lamellar phase.

Highly inhomogeneous fields have been taken to the extreme in the case of one-sided (also called unilateral or inside out) NMR probes. Originally developed by the oil industry for investigating the regions around bore holes, they are now produced by several companies and have numerous applications. The most well-known is the handheld NMR Mouse (**Figure 4**) developed by Bernhard Blumich and collaborators and sold by ACT GmbH.

The NMR Mouse and similar probes are designed to detect nuclear spins from a region *outside* the probe. With suitably organized permanent magnets, it is possible to produce a reasonably uniform field remote from the surface of the probe. An appropriately configured RF coil can then be used to excite these spins. Because the (B_1/I) factor is very poor in these probes when compared with conventional (outside-in) NMR probes, the SNR from a single scan can be quite poor (sometimes less than 1). However, the one-sided nature of these probes means that arbitrarily large objects can be investigated – something impossible with conventional NMR equipment.

The NMR Mole (MOBILE Lateral Explorer) shown in **Figure 5** produces a sweet spot ~ 15 –20 mm above the surface of the magnet and operates at 3.2 MHz. Because the line-width is ~ 10 kHz the RF pulse requirements are not excessive – a 10 W 40 μ s pulse is sufficient. An SNR of 20 from a single scan is possible with this probe. Applications include food quality control and moisture content measurements.

Rather than going for a uniform field in all three dimensions, the NMR Mouse produces a uniform field in

Figure 2 CPMG decay curves and relaxation spectra for a hard (*top*) and soft (*bottom*) rubber sample.

Figure supplied by Hubbard PL, McGrath KM, and Callaghan PT (2005) A study of anisotropic water self-diffusion and defects in the lamellar mesophase. *Langmuir* 21: 4340–4346.

Figure 4 The NMR Mouse – a handheld one-sided probe produced by ACT GmbH.

only two – leaving a strong field gradient above the probe face – this means that different planes above the probe face will have different resonant frequencies. These planes can be accessed by retuning the probe and spectrometer or by using a fixed frequency and moving the sample. In this way, high-resolution 1-D images may be obtained along the vertical axis. Resolutions of the order of micrometers are possible using the NMR Mouse with lift (**Figure 6**). When combined with horizontal plane gradients, full 3-D imaging is possible although the resolution in the horizontal plane will be lower.

Because of the low-field homogeneity produced by the NMR Mouse, the line-width is much larger than in the NMR Mole – typically ~ 300 kHz and so short RF pulses are advantageous as they excite larger spin volumes – a 100 W $4\mu\text{s}$ RF pulse is typical. The SNR is similar to the Mole because the sweet spot is much closer to the probe

Figure 5 The NMR Mole (on left) – a one-sided NMR probe produced by Magritek Ltd.

Figure 6 ACT Profile Mouse and Lift showing a 1-D image of two latex films $60\text{ }\mu\text{m}$ thick, separated by a $160\text{ }\mu\text{m}$ glass spacer. This magnet has a built-in vertical field gradient of 11 T m^{-1} .

Figure 7 A conventional spin-echo signal from the NMR Mouse obtained with 64 accumulations and a total experiment time of 13 s (*top*). Four accumulations of 32 CPMG echoes added together – experiment time 0.8 s (*bottom*).

– typically less than 2 mm and consequently the field is much stronger. However, the Mouse is much smaller (1 kg *cf* 10 kg) and can be easily held in one hand. This highlights a problems with all unilateral probes – the further away the sweet spot, the larger (and heavier) the probe, the larger the RF power requirements, and the lower the SNR.

Experiments to Enhance SNR

Although the signal from unilateral probes is quite weak, a clever trick can be used to recover signal to noise. This

involves performing a CPMG experiment with a short ($< 100\text{ }\mu\text{s}$) echo time. If the sample has a relatively long T_2 , many hundreds or even thousands of echoes can be produced. By coadding these echoes, the time domain SNR can be enhanced many times. This method can be used instead of the normal 90° pulse or spin-echo detection used by a variety of sequences. **Figure 7** shows some examples, demonstrating the improved SNR obtained using this technique. The data were obtained using a rubber sample and an NMR Mouse. Echo time was $100\text{ }\mu\text{s}$. $T_2 = 2.3\text{ ms}$ and $T_1 = 60\text{ ms}$.

Figure 8 The portable Lapspec NMR spectrometer (*center*) with NMR Mouse and equally small laptop. This system operates from 1 to 30 MHz with an RF output power of ~ 100 W.

Figure 9 An FID and corresponding spectrum obtained from a 500 ml sample in the Earth's magnetic field using 18 mT of prepolarization. Shimming has been applied to allow the apparatus to run indoors.

Portable Systems for One-Sided NMR

One of the attractions of one-sided NMR is the possibility of making completely portable equipment. Traditionally, spectrometers for NMR are large machines consisting of a console containing a computer, monitor, and a rack of electronics, which might weight as much as 100 kg. However, using today's modern electronics, the whole spectrometer, including high-powered RF amplifier, can be packaged in a unit no larger than a typical laptop. Such a system, the Lapspec, is shown in the **Figure 8** and was developed by Magritek and ACT. This type of spectrometer owes its existence to efficient

switched-mode power supplies and to the explosive growth of cell phone technology that has lowered the cost and size of dedicated digital receivers and digital synthesizers. A more recent technological phenomenon has been the availability of cheap field-programmable gate arrays (FPGAs). These consist of thousands to millions of logic gates that can be connected in a variety of ways so as to implement almost any desired digital function. They are particularly useful when implementing functions, that must run in parallel – something difficult to do on a microprocessor, but which are essential if concurrent processes are to occur in an NMR pulse sequence.

Figure 10 A comparison of the EFNMR spectrum obtained with and without prepolarization. The signal is ~ 300 times more intense in the upper plot – close to the expected 350-fold increase in sensitivity. (These experiments were done without shimming to ensure no contamination of the Earth's magnetic field – hence the broader line.)

Figure 11 The Terranova, the equipment Magritek has developed to perform EFNMR. The probe on the left consists of three concentrically mounted coil sets. Outside is an air-cored electromagnet for producing the 18 mT prepolarizing field, a set of first-order shims and a B_1 coil for detecting the FID. The latter has several thousand turns of fine wire to provide the high B_1/I and Q factor necessary to maximize sensitivity. On the right is a computer-controlled low-frequency spectrometer for generating all the necessary pulses and for collecting, amplifying, and digitizing the NMR signal.

Sub-Megahertz NMR

Although theoretically unilateral NMR can be made to work at arbitrarily distant points from the probe surface, a point is reached at which the RF power requirements become excessively high. For example, in oil well logging

the sweet spot may be many centimeters away from the probe face, resulting in extremely low B_1/I values and very low resonant frequencies – typical in the 100 kHz range. In this case, several kilowatts of RF power may be required to excite the spins and the returned signal will be extremely small. Where possible NMR at these

Figure 12 CPMG experiment performed using EFNMR to determine the transverse relaxation time of a water sample.

Figure 13 The EFNMR probe used to perform *in situ* measurements of Antarctic sea ice brine content and porosity. An additional gradient coil is included to perform self-diffusion measurements. A relatively high value for the Earth's magnetic field, low temperatures, and a low background noise provided an ideal environment for performing these experiments.

frequencies is more conveniently performed using conventional solenoid geometries and air-cored electromagnets with the sample mounted inside the probe, thereby reducing the RF power requirements and maximizing the received signal.

An example of this is Earth's field NMR (EFNMR). Here, the field of interest is $\sim 50 \mu\text{T}$ corresponding to a resonant frequency of $\sim 2 \text{ kHz}$ for protons. At this field strength, it is very difficult to observe NMR due to the

extremely small thermally induced magnetization and the inefficiency of Faraday detection at low frequencies (as shown in **Figure 10**). From eqn [2], it can be seen that if field strength is considered alone then the detected signal amplitude will be 250 000 times less than at 1 MHz ($\sim 23 \text{ mT}$).

A number of solutions to the sensitivity problem have been suggested. The first and the simplest is to increase the polarizing field B_p artificially while leaving the

Figure 14 A 3-D image of a mandarin orange with cross-sections obtained using EFNMR. Imaging time was 4 h and the field of view 110 mm.

detection field unchanged. Apart from the increase in magnetization this provides, it also allows large sample volumes to be used if the detection field is reasonably homogeneous (the homogeneity of the polarizing field is far less important). Away from built-up areas or with the addition of simple first-order shim coils, the Earth's magnetic field is uniform to better than one part in a 10 000 over relatively large volumes. This may not sound very good when compared with the homogeneity available in high-field instruments (typically measured in parts per billion) until one realizes that the natural line-width of most nuclear transitions in liquids is in the range of 0.1–10 Hz.

Figure 9 is an example of single-scan FID and spectrum from a 500 ml sample of tap water prepolarized by an electromagnet producing an 18 mT field (corresponding to a 350-fold increase in sensitivity). The magnetization is then returned adiabatically to the Earth's field direction after which a conventional NMR pulse and collect sequence are applied to detect the precessing magnetization at ~ 2 kHz. A signal level of 100 μ V is typical with an SNR of between 10 and 40 depending on the ambient external noise level (**Figure 10**).

Figure 15 A ^{19}F - ^1H COSY of 2,2,2-trifluoroethanol doped with 1.5 mM TEMPO acquired in the Earth's field with DNP irradiation at 131.5 MHz in a prepolarization field of 2.5 mT. Total experiment time was 11 h. From Halse ME and Callaghan PT (2008) A dynamic nuclear polarization strategy for multi-dimensional Earth's field NMR spectroscopy. *Journal of Magnetic Resonance* 195: 162–168, with permission.

Figure 16 Single-shot ^3He lung images taken at a field of 6.5 mT (210 kHz). Total imaging time is 4 s for the 2-D plots and 33 s for the 3-D plot. From Tsai LL, Mair RW, Rosen MS, Patz S, and Walsworth RL (2008) An open-access, very-low-field MRI system for posture-dependent ^3He human lung imaging. *Journal of Magnetic Resonance*. 193: 274–285, with permission.

Figure 17 Single-scan EFNMR pulse and collect experiments performed with a 100 mL water sample doped with 1 mM TEMPO. The top plot is a conventional 18 mT prepolarized FID that due to the smaller sample has about one-fifth of the signal amplitude seen in **Figure 9**. In the lower image, there is no prepolarization and the signal amplitude is about six times better than that obtained using an 18 mT prepolarizing field. The TEMPO has therefore resulted in a $350 \times 6 = 2100$ times signal enhancement relative to 50 μT polarization alone (Compare this with the lower plot in **Figure 10**.)

A variety of NMR experiments, with the exception of chemical shift-resolved spectroscopy (impossible at these frequencies), are possible with this apparatus (**Figure 11**). The CPMG experiment mentioned earlier is easily demonstrated (**Figure 12**) along with experiments to determine T_1 . It is even possible to listen to the FID directly since the resonant frequency falls into the audio range!

Owing to the low operating frequencies, external noise sources are a serious problem with the Earth's field method and have resulted in most of the original experiments being performed far away from human activities. Although the Terranova ENMR apparatus is now primarily sold as a teaching tool, the original application

was to measure self-diffusion of brine water trapped in Antarctic sea ice (see **Figure 13**). The low-noise environment and highly homogeneous detection field produced good quality albeit chilly measurements! However, by surrounding the probe by a 10 mm-thick aluminum shield (the skin depth at 2 kHz is several mm!) and shorting out the polarizing coil during the detection phase of the experiment, noise attenuation factors of several 100 are possible, allowing operation in many urban locations. Although it may be difficult to shield noise at such low frequencies, the ability of the Earth's magnetic field to penetrate thin metal has an application – it is possible, for example, to measure NMR signals from the contents of a thin aluminum can without significant attenuation (see

Figure 18 Image of a human hand made using a multichannel SQUID detector at a field of $46\ \mu\text{T}$. From Zotev VS, Volegov PL, Matlashov AN, Espy MA, Mosher JC, and Kraus RH (2008) Parallel MRI at microtesla fields. *Journal of Magnetic Resonance* 192: 197–208, with permission.

the section on SQUID detection). This is something that would be impossible at higher fields.

Imaging at Earth's Field

The Terranova's three shim coils can be made to double as gradient coils and so can be used to perform 2-D and 3-D imaging experiments (see, for example, **Figure 14**). At these low magnetic fields, the broadening required to perform imaging is only a few tens of Hertz requiring very weak gradients and consequently low currents. Also because the Larmor frequency is very low, the system can perform heteronuclear experiments without probe re-tuning. This has been used to demonstrate heteronuclear J coupling in both 1-D and 2-D experiments (**Figure 15**).

Polarization Transfer Methods for Enhancing SNR

Because the detected signal strength drops off precipitously as the field moves into the millitesla and microtesla regions, a variety of techniques have been devised to enhance the signal level. The first that is considered is hyperpolarization. In one case, a highly polarized sample of inert gas such as ^3He or ^{129}Xe is prepared using optical polarization transfer methods. This can result in nuclear polarizations four or five orders of magnitude larger than provided by thermal polarization alone. This gas is then introduced to the structure to be studied, such as the human lung, and then conventional imaging is performed. Even though the detection may be performed at a low field to minimize magnetic susceptibility effects

and the spin density is low, the large magnetization compensates for this, resulting in high-quality images, which can be difficult or impossible to obtain in other ways. It should be noted, however, that although the imaging system can be relatively inexpensive if it operates at low field, the preparation and transport of the hyperpolarized gas can be a complex process (**Figure 16**).

The second method of signal enhancement is dynamic nuclear polarization (DNP). In this case, the sample being studied has been doped with a chemical such as 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO), which is a nitroxide free radical. The DNP mechanism occurs via the Overhauser effect, where the polarization of electron spins in the TEMPO (excited by applying continuous high-frequency RF energy) are transferred via electron–proton dipolar relaxation to protons in the surrounding environment. The resultant enhancement in the magnetization may again be several orders of magnitude. Commercial EFNMR magnetometers typically use DNP to remove the requirement for bulky prepolarizing coils. **Figure 17** demonstrates the superior performance of DNP compared to prepolarization.

Ringdown at Low Frequencies

In addition to the problem of poor SNR, low fields and their correspondingly low frequency detection pose other difficulties. One of these is long B_1 coil ringdown times. The B_1 coil forms part of a resonant circuit so as to improve the amplitude of the detected signal. The quality factor or Q is the ratio of the detected signal on resonance to that obtained without the tuned circuit. The noise level also increases with Q , but in such a way that overall signal level with a matched *or* nonmatched B_1 coil increases as the square root of Q (see eqn [3]). A high Q is therefore clearly an advantage. However, a high Q means that following an RF pulse the coil will ring excessively, that is, the energy in the coil will decay exponentially with a time constant given by $\tau = 2Q/\omega$. After 10–20 time constants, the ringdown is generally insignificant. At high frequencies, the time is typically a few microseconds or less. However, in the Earth's field apparatus it is 25 ms! This limits the kinds of experiments that can be performed or samples that can be investigated, since one must wait this length of time before detecting the signal. One way around this problem is to avoid resonant detection – but unless one uses a non-Faraday form of detection (see the section on SQUID Detection) this will result in severe SNR loss. An alternative solution is to actively damp the ringdown (i.e., artificially reduce the Q) for a short time following the RF pulse. This can make enormous differences in those cases where samples have short relaxation times (this method is used with the 2 MHz rock core analyzer in **Figure 1** to enhance the SNR).

Figure 19 (a) SQUID MR images of a bell pepper showing six cross-sections – each with an 8 mm thickness. (b) Six cross-sections of the same pepper enclosed in an aluminum can demonstrate the penetrating power of NMR at these frequencies. In each case, $B = 66 \mu\text{T}$. From Mölle M, Han S, Myers WR, et al., 2006. SQUID-detected microtesla MRI in the presence of metal *Journal of Magnetic Resonance* 179: 146–151, with permission.

High Q coils also restrict the bandwidth at low frequencies – another reason for considering nonresonant detectors.

SQUID Detection

As mentioned earlier, the efficacy of Faraday detection is such that the lower the resonant frequency the less signal one obtains, even with prepolarization or other forms of magnetization enhancement. An alternative solution is to use other forms of detection. One of these, which is popular because of its unprecedented sensitivity, is the SQUID. SQUIDs have the property of detecting the

magnetic flux directly, rather than its rate of change, as is the case for Faraday detection. For proton resonance frequencies below several megahertz, this will be more sensitive than Faraday detection. At extremely low frequencies ($<100 \text{ Hz}$), they are really the only practical way of making NMR measurements (although recent optical techniques promise even higher sensitivity). Because SQUIDs require a superconducting environment, the sample must be thermally isolated from the detection coil. Their sensitivity is perhaps most strongly demonstrated in the measurements made of ‘brain waves,’ that is, the detection of currently flowing through neural pathways in the brain (MEG). Because it can be difficult to determine the source of these currents, there is much

Figure 20 The spectrum obtained from a polycrystalline material is characterized by a broad line due to the variety of dipolar couplings and lack of motional averaging that would occur in a liquid. Figure 21 At zero field, the dipolar broadening is removed since all nuclei see an identical external magnetic environment allowing the resulting spectrum (*lower left*) to be matched against one of three possible models (*lower right*). From Thayler AM and Pines A (1987) Zero-field NMR. *Accounts of Chemical Research* 20(2): 47–53, with permission.

interest in combining MEG and MRI; however, the large fields generated by the MRI machine would wreak havoc on the sensitive MEG measurements, and so low-field MRI systems are being investigated, which use SQUID detectors to enhance sensitivity and therefore resolution. An example of the sort of image quality possible is shown in **Figures 18 and 19** – the imaging here is performed in at field strength similar to the Earth's. Of course it is possible to combine SQUID detection with the various forms of magnetization enhancement described earlier to create a low-field system with all the sensitivity of a high-field spectrometer.

Zero-Field NMR

The ultimate in low-field NMR must be no field at all. One might wonder what possible use this might serve since from eqns [1] and [2] at zero field there will be zero magnetization. However, there is a class of experiments that benefits from removing the field – at least for part of the experiment. One such is the measurement of ‘powder spectra’ pioneered by Alex Pines and coworkers. Nuclei in polycrystalline or amorphous solids tend to produce broad spectra because the dipolar fields generated by neighboring nuclei will vary depending on their orientation with

respect to the applied field. The result is a superposition of many different spectra, giving rise to broad featureless data (see **Figure 20**). At zero field, the orientation of these dipolar fields is no longer of significance leaving sharp spectra similar to those that would be observed from a single crystal. Because the sensitivity at zero field will be close to zero, the sample is polarized and the signal detected at a relatively high-field strength. For a short time during the experiment the field is dropped to zero – either electrically or mechanically by moving the sample out of the magnet. If this duration is systematically varied, then a Fourier transform of the collected data in this second dimension will reveal the desired spectrum (see **Figure 21**).

Summary

Although many researchers will continue to pursue higher-field NMR where high sensitivity and spectral resolution are mandatory, there still exist niches in which low fields or low resolution can be of use, whether because of sample access reasons (one-sided NMR), environmental sensitivity (SQUID MRI combined with MEG), low cost (EFNMR), or susceptibility problems (hyperpolarized lung imaging). In particular, many industrial applications require robust and relatively inexpensive instruments that are simple to use – this is an area in which significant growth for low-field systems is expected. A variety of potential applications also exist in medical science from handheld blood analysis units to portable MRI systems.

Introduction

Luminescence refers to the emission of light from an excited electronic state of a molecular species. In the case of photoluminescence, a molecule absorbs light of wavelength λ_1 decays to a lower energy excited electronic state, and then emits light of wavelength λ_2 , as it radiatively decays to its ground electronic state. Generally, the wavelength of emission, λ_2 , is longer than the excitation wavelength but in resonance emission $\lambda_1 = \lambda_2$. Luminescence bands can be either fluorescence or phosphorescence, depending on the average lifetime of the excited state which is much longer for phosphorescence than fluorescence. The relative broadness of the emission band is related to the relative difference in equilibrium distance in the excited emitting state versus the ground electronic state.

Photoluminescence of a molecular species is different from emission of an atomic species. In the case of atomic emission, both the excitation and the emission occur at the same resonance wavelength. In contrast, excitation of a molecular species usually results in an emission that has a longer wavelength than the excitation wavelength.

If a chemical reaction results in the production of a molecular species in an excited electronic state that emits

light, this phenomenon is termed chemiluminescence. Chemiluminescence usually occurs in the gas or liquid phase. In contrast, photoluminescence can occur in the gas, liquid or solid phases.

The next two sections provide a discussion of the basic principles of luminescence spectroscopy, which include the electronic transitions and the important parameters determined from luminescence measurements. Then follow two sections that describe the general characteristics of luminescence measurements and one which provides two case studies for organic and inorganic luminophores. The remainder of the article covers more specific topics and phenomena in luminescence spectroscopy, namely quenching, energy transfer, exciplexes and chemiluminescence. The examples in this article were selected to cover multidisciplinary areas of science.

Electronic Transitions and Relaxation Processes in Molecular Photoluminescence

The Jablonski Energy Level Diagram

The radiative and non-radiative transitions that lead to the observation of molecular photoluminescence are typically illustrated by an energy level diagram called the Jablonski diagram. **Figure 1** shows a Jablonski diagram that explains the mechanism of light emission in most organic and inorganic luminophores. The spin multiplicity of a given electronic state can be either a singlet (paired electrons) or a triplet (unpaired electrons). The ground electronic state is normally a singlet state and is designated as S_0 in **Figure 1**. Excited electronic states are either singlet (S_1 , S_2) or triplet (T_1) states.

When the molecule absorbs light an electron is promoted within 10^{-14} – 10^{-15} s from the ground electronic state to an excited state that should possess the same spin multiplicity as the ground state. This excludes a triplet excited state as the final state of electronic absorption because the selection rules for electronic transitions dictate that the spin state should be maintained upon excitation. A plethora of non-radiative and radiative processes usually occur following the absorption of light en route to the observation of molecular luminescence. The following is a description of the different types of non-radiative and radiative processes.

Figure 1 The Jablonski diagram. Radiative and non-radiative processes are depicted as solid and dashed lines, respectively.

Non-Radiative Relaxation Processes

Vibrational Relaxation

Excitation usually occurs to a higher vibrational level of the target excited state (see below). Excited molecules normally relax rapidly to the lowest vibrational level of the excited electronic state. This non-radiative process is called 'vibrational relaxation'. Vibrational relaxation processes occur within 10^{-14} – 10^{-12} s, a time much shorter than typical luminescence lifetimes. Therefore, such processes occur prior to luminescence.

Internal Conversion

If the molecule is excited to a higher-energy excited singlet state than S_1 (such as S_2 in **Figure 1**), a rapid non-radiative relaxation usually occurs to the lowest-energy singlet excited state (S_1). Relaxation processes between electronic states of like spin multiplicity such as S_1 and S_2 are called 'internal conversion'. These processes normally occur on a time scale of 10^{-12} s.

Intersystem Crossing

Non-radiative relaxation processes between different excited states are not limited to states with the same spin multiplicity. A process in which relaxation proceeds between excited states of different spin multiplicity is called 'intersystem crossing'. The relaxation from S_1 to T_1 in **Figure 1** is an example of an intersystem crossing.

Intersystem crossing is generally a less probable process than internal conversion because the spin multiplicity is not conserved. Because of the lower probability for intersystem crossing processes they occur more slowly ($\sim 10^{-8}$ s) than internal conversions. Intersystem crossing processes become more important in molecules containing heavy atoms such as iodine and bromine in organic luminophores and metal ions in inorganic luminophores (transition-metal complexes). Significant interaction between the spin angular momentum and the orbital angular momentum (spin-orbit coupling) becomes more important in the presence of heavy atoms and, consequently, a change in spin becomes more favourable. In solution, the presence of paramagnetic species such as molecular oxygen increases the probability of intersystem crossing. In transition metal complexes, intersystem crossing processes become increasingly important as one proceeds from complexes of the 3d-block elements to those of the 4d- and 5d-blocks.

Non-Radiative De-Excitation

The excitation energy stored in the molecules following absorption must be dissipated owing to the law of conservation of energy. The aforementioned non-radiative processes occur very rapidly and only release very small amounts of energy. The rest of the stored energy will be dissipated either radiatively, by emission of photons (luminescence), or non-radiatively, by the release of thermal

energy. The non-radiative decay of excitation energy which leads to the decay of the excited molecules to the ground electronic state is called 'non-radiative de-excitation'. These processes result in the release of infinitesimal amounts of heat that cannot normally be measured experimentally. The experimental evidence for non-radiative de-excitation processes is the quenching of luminescence. A major route for non-radiative de-excitation processes is energy transfer to the solvent or non-luminescent solutes in the solution. In the solid state, crystal vibrations (phonons) provide the mechanism for non-radiative de-excitation.

Radiative Processes: Fluorescence and Phosphorescence

The spin selection rule for electronic transitions (both absorption and emission) states that 'spin-allowed' transitions are those in which the spin multiplicity is the same for the initial and final electronic states. Therefore, spin-allowed transitions are more likely to take place than spin-forbidden transitions. 'Fluorescence' refers to the emission of light associated with a radiative transition from an excited electronic state that has the same spin multiplicity as the ground electronic state. Fluorescence is depicted by the radiative transition $S_1 \rightarrow S_0$ in **Figure 1**. Since fluorescence transitions are spin-allowed, they occur very rapidly and the average lifetimes of the excited states responsible for fluorescence are typically $<10^{-6}$ s.

Electronic transitions between states of different spin multiplicity are 'spin-forbidden' which means that they are less probable than spin-allowed transitions. However, spin-forbidden transitions become more probable when spin-orbit coupling increases. The factors that increase the probability of phosphorescence are the same factors discussed above that increase the probability of intersystem crossing. Therefore, if the triplet excited state is populated by intersystem crossing then luminescence might occur from the triplet state to the ground state. 'Phosphorescence' refers to the emission of light associated with a radiative transition from an excited electronic state that has a different spin multiplicity from that of the ground electronic state. Phosphorescence is depicted by the radiative transition $T_1 \rightarrow S_0$ in **Figure 1**. Since phosphorescence transitions are spin-forbidden, they occur slowly and the average lifetime of the excited states responsible for phosphorescence typically range from 10^{-6} s to several seconds. Therefore, some textbooks refer to phosphorescence as 'delayed fluorescence'. Photoluminescence refers to both fluorescence and phosphorescence.

Excited-State Distortions and the Franck-Condon Principle

Luminescence spectroscopy can be used to gain information about the geometry of a molecule in an excited

electronic state. Such information provides an understanding of the difference in the bonding properties of an excited state relative to the ground state. These properties can be better understood when the electronic transitions are discussed in the context of the potential surfaces of the ground and excited states.

Electronic absorption of light occurs within 10^{-15} s. Since this time is extremely short, the nuclei are assumed to be 'frozen' during the time scale of absorption. Therefore, the transitions between various electronic levels are depicted as 'vertical' transitions in energy level diagrams. This assumption of negligible nuclear displacement during electronic transitions is known as the 'Franck–Condon principle'. **Figure 2** illustrates the Franck–Condon principle. Electronic excited states usually have different geometries than the ground state and, consequently, different equilibrium distances. Since electronic transitions are vertical, only transition A in **Figure 2** occurs. Transition C involves an excited state that is largely displaced from the ground state and thus no vertical transition is possible to this state. Transition B, on the other hand, terminates in the lowest vibrational level of the excited state. **Figure 2** shows that this transition cannot occur vertically, either. The three transitions depicted in **Figure 2** explain why in the Jablonski diagram (**Figure 1**): (i) the absorption was depicted to a higher vibrational level of the S_2 excited state than the $v = 0$ level, and (ii) no direct excitation to the triplet excited state (T_1) was depicted.

Usually, the nuclei of excited molecules are displaced from their ground state positions. The displacement is caused by differences in the bonding properties between

Figure 2 The Franck–Condon principle. Only vertical electronic transitions are allowed.

the molecular orbitals that represent the ground and excited states, respectively. The extent of the nuclear displacement varies from one case to another. **Figure 3** illustrates two cases (a) and (b) of excited state distortion. The transitions depicted in **Figure 3** are called 'vibronic transitions'. A vibronic transition refers to a transition that involves a change in both electronic and vibrational states.

The case shown in **Figure 3(b)** represents an extreme case in which the excited state distortion is virtually zero. As a result, the electronic transition for which $v = 0$ in both the ground and excited states (called the 0–0 vibronic transition) has the greatest probability and, thus, the strongest intensity in both absorption and emission spectra. When excited state distortion is significant, as in **Figure 3a**, the 0–0 transition becomes much less probable and so its intensity becomes much weaker than other 0– v vibronic transitions with higher v values.

The probability (P) of the occurrence of a vibronic transition is proportional to the square of the *Franck–Condon factor*, which is defined as the overlap integral of the vibrational wavefunctions, $\Psi(v)$. Therefore,

$$P \propto |\langle \Psi(v_1) | \Psi(v_2) \rangle|^2 \quad [1]$$

In many instances the absorption and emission maxima correspond to the same (v_1 – v_2) vibrational pair. For example, **Figure 3a** shows that the 0–2 vibronic transition has the strongest intensity in both the absorption and the emission spectra. This is called the 'mirror image' rule and is followed by luminophores whose excited state distortion is zero or small. However, the mirror image rule may not apply for cases where large excited state distortion exists. Examples of each case are provided in the section dealing with organic luminophores.

Quantitative information about excited state distortion can be obtained from the luminescence spectra. For cases where vibronic structure is observed, the excited state distortion can be probed qualitatively simply by identifying the most intense vibronic transition: the larger the value of the vibrational level of the excited state, the larger the excited state distortion (as illustrated in **Figure 3**). Quantitatively, the displacement (Δq) of the excited state equilibrium distance from the corresponding ground state distance can be calculated. The procedure involves the calculation of the Franck–Condon factor as a function of Δq for each vibronic transition. This results in a calculated emission spectrum, which can be compared with the experimental emission spectrum as a function of Δq until a good fit is obtained. The actual Δq would be the value that gives the best fit.

The emission (and absorption) spectra in many practical cases do not show resolved vibronic peaks. This is especially the case in solutions of the luminophores at ambient temperatures. The interaction of excited molecules of the luminophore with solvent molecules (especially polar

Figure 3 Potential energy diagrams for two cases of excited state distortions: (a) non-zero distortion and (b) zero distortion. The corresponding absorption and emission spectra are shown below. Reproduced with permission from Adamson AW and Fleischauer PD (1975) *Concepts of Inorganic Photochemistry*, p. 4. New York: Wiley-Interscience.

solvents) is responsible for this broadening. There are methods to quantify Δq in these cases with the aid of some computer programs, but the description of these methods is beyond the scope of this article. In the section on inorganic exciplexes, nevertheless, we provide an example in which Δq is evaluated theoretically for a system that exhibits structureless emission bands.

Another quantitative measure of excited state distortion is the *Stokes shift*, defined as the energy difference between the emission and absorption peak maxima for the same electronic transition. The lower part of **Figure 3a** illustrates how the Stokes shift is evaluated in typical cases. The Stokes shift of the rare case shown in **Figure 3b** is zero because the absorption and emission spectra have the same peak positions. The band width can also be used to quantify excited state distortions. The band width is normally quantified in terms of the full-width-at-half-maximum (fwhm). The value of fwhm is calculated as the energy difference between the band positions that have intensities equal to one half the peak maximum, assuming a gaussian shape is obtained for the emission band. In the absence of excited state distortions the emission bands appear as sharp peaks with very small fwhm values (**Figure 3b**), whereas in more common cases the electronic bands are much broader because of excited state distortions (**Figure 3a**). In those cases where the emission spectra are devoid of vibronic structure, the fwhm values are calculated for the whole broad band. The Stokes shift and fwhm are parameters for

excited state distortion because their values are larger for 0- ν vibronic transitions with higher ν values. The Stokes shift and fwhm are especially useful in cases where the emission spectra are structureless, because of the difficulty of carrying out the Δq calculation in such cases.

Emission and Excitation Spectra

In luminescence spectroscopy the emission of the luminophore is monitored. There are two different types of luminescence spectra that can be recorded with modern spectrofluorometers, emission and excitation spectra. Note that although the name implies that these instruments measure only fluorescence, spectrofluorometers can also measure phosphorescence, especially when special accessories are added. Spectrofluorometers contain both an excitation monochromator and an emission monochromator. In emission spectra, the excitation wavelength is fixed and the emission monochromator is scanned. The excitation is usually fixed at a wavelength at which the sample has significant absorbance. In excitation spectra, on the other hand, the emission wavelength is fixed and the excitation monochromator is scanned. The emission is normally fixed at a wavelength that corresponds to the emission peak of the sample.

Theoretically, the excitation spectra should mimic the absorption spectra of the luminophores. However, the

lamp output is wavelength-dependent. For example, a common light source in modern spectrofluorometers is a xenon lamp. The output of this lamp is a continuum in the range ~ 200 – 1200 nm. The radiation curve approximates blackbody radiation with a maximum near 550 nm and a sharp decline at short wavelengths. A correction is, therefore, needed for the lamp background in order for the excitation spectra to correlate with the absorption spectra. Corrected excitation spectra are usually obtained by using a *quantum counter*, a strong luminophore capable of absorbing virtually all incident light over a wide range of wavelength. Rhodamine B is a commonly used quantum counter. Concentrated solutions of rhodamine B absorb virtually all the incident light in the 220 – 600 nm range. The excitation spectrum of rhodamine B monitoring its emission maximum (633 nm) is determined only by the lamp output in the 220 – 600 nm range (Figure 4a).

Corrected excitation spectra of luminophores are obtained by dividing the uncorrected spectra by the excitation spectrum of the quantum counter. A common improvement in the corrected excitation spectra versus the uncorrected spectra is to eliminate the sharp 'spikes' of the xenon lamp between 450 and 500 nm (Figure 4(a)). This makes the excitation spectra of many luminophores very similar to their absorption spectra. However, more dramatic differences may exist, especially for luminophores

which absorb in the UV region. An example of such a luminophore is the silver complex $[\text{Ag}(\text{CN})_2]^-$. Figure 4b shows the corrected and uncorrected excitation spectra of $[\text{Ag}(\text{CN})_2]^-$ doped in NaCl crystals. Note that the corrected excitation spectra are significantly different from the uncorrected spectra. This difference is attributed to the low output of the xenon lamp at wavelengths shorter than 280 nm (Figure 4a), at which $[\text{Ag}(\text{CN})_2]^-$ species absorb strongly.

Absorption and excitation spectra are complementary. The necessity to obtain a correction for the excitation spectra represents a disadvantage. There are advantages, however, for excitation spectra over absorption spectra. The much higher sensitivity of luminescence techniques compared to absorption techniques is an obvious advantage for excitation spectra. The greater sensitivity of luminescence techniques stems from the fact that the luminescence intensity can be enhanced by increasing the intensity of the excitation source, which is not the case in absorption. The greater sensitivity of luminescence techniques is, however, accompanied by less precision compared to absorption techniques. The relative ease of acquiring excitation spectra for some materials such as solids represents another advantage over absorption measurements. Finally, excitation spectra can provide valuable information about excited state processes such as energy transfer (see below) that cannot be obtained by absorption spectra.

Luminescence Lifetimes

Theory

Consider the simplest case in which a molecule A absorbs light and is in an excited electronic state denoted by *A . If the molecule has a single pathway for decay, say fluorescence, we can write the following equation:

This is a first-order process whose rate can be expressed mathematically as:

$$-d[^*A]/dt = k_f[^*A] \quad [3]$$

where k_f is the rate constant of the fluorescence decay (eqn [2]). The reciprocal of k_f is called the fluorescence lifetime τ_f ($\tau_f = 1/k_f$). Integration of eqn [3] gives:

$$[^*A] = [^*A]_0 \exp(-t/\tau_f) \quad [4]$$

Hence, a plot of $\ln [^*A]$ versus time (t) should give a straight line with a slope of $1/\tau_f$. The value of $[^*A]$ is determined from the fluorescence intensity. Experimentally, lifetime measurements are obtained using a pulsed laser source. Pulsing leads to the population of the excited state of A, followed by emission of light by *A with a time profile

Figure 4 Correction of the excitation spectra by the quantum counter method: (a) excitation spectrum of rhodamine B; (b) excitation spectra of $[\text{Ag}(\text{CN})_2]^-/\text{NaCl}$ doped crystals monitoring the emission at different wavelengths. Corrected and uncorrected spectra are shown as thick and thin lines, respectively.

according to eqn [4]. **Figure 5** shows a schematic description of a luminescence decay curve (a) and the plot used for the determination of the excited state lifetime (b).

Next, consider the case where *A can exhibit fluorescence (eqn [2]) and also non-radiative decay:

with a rate constant of k_{nr} . The decay of *A can now be described as:

$$-d[^*A]/dt = k_f[^*A] + k_{nr}[^*A] = (k_f + k_{nr})[^*A] \quad [6]$$

In this case the lifetime τ becomes:

$$\tau = 1/(k_f + k_{nr}) \quad [7]$$

or the reciprocal of the sum of k_f and k_{nr} .

Generally, the non-radiative rate constant decreases at lower temperatures. As the temperature (T) approaches absolute zero, τ approaches $1/k_f$. A plot of $1/\tau$ versus T extrapolated to $T = 0$ K allows one to determine k_f as the value of the intercept (see the example in the case study on inorganic luminophores). Therefore, the value of the fluorescence lifetime (τ_f) is determined as $1/k_f$. Note that the treatment described in this section applies for both fluorescence and phosphorescence lifetimes and not just for fluorescence.

Figure 5 Experimental determination of excited state lifetimes: (a) a plot of the intensity (I) versus time after the laser pulse. The lifetime corresponds to the time at which the intensity decays to $1/e$ of its maximum value; (b) a plot of $\ln(I)$ versus time after laser pulse. The lifetime here can be calculated directly from the slope of the linear equation.

Now consider a final lifetime case in which two states are thermally populated at a temperature T . If excited state 1 has a lifetime τ_1 and excited state 2 has a lifetime τ_2 , the observed lifetime τ_{obs} will be a weighted average of the two lifetimes:

$$\tau_{obs} = (n_1/N)\tau_1 + (n_2/N)\tau_2 \quad [8]$$

with $N = n_1 + n_2$. Assuming that excited states 1 and 2 are non-degenerate and using the Boltzmann distribution function gives:

$$\tau_{obs} = \{\tau_1 + \tau_2 \exp(-\Delta E/kT)\} / [1 + \exp(-\Delta E/kT)] \quad [9]$$

where ΔE is the energy difference between states 1 and 2 and k is the Boltzmann constant. Fitting τ_{obs} versus T to eqn [9] allows the determination of the value of ΔE as well as τ_1 and τ_2 .

Fluorescence versus Phosphorescence Lifetimes

A major advantage of luminescence lifetime measurements is their use for spectral assignment. Specifically, the assignment of the luminescence bands as fluorescence or phosphorescence is primarily determined via luminescence lifetime measurements. As a rule of thumb, lifetimes on the order of micro-seconds and longer (milliseconds, seconds) are normally indicative of phosphorescence, while fluorescence lifetimes are normally on the sub-microsecond level (nanoseconds, picoseconds etc). It should be noted, however, that fluorescence and phosphorescence lifetime values vary from one case to another, depending on the system under study as well as other factors such as the extent of excited state distortion. This causes some subjectivity in the assignment, especially when the measured lifetimes are at borderline levels between the aforementioned levels of fluorescence and phosphorescence lifetimes. The clearest cases are those in which fluorescence and phosphorescence bands are both present in one system. In these cases, the phosphorescence bands exhibit lifetimes that are orders of magnitude longer than the lifetimes of the corresponding fluorescence bands. An example is given for such a case in the section on inorganic luminophores.

Luminescence Quantum Yields

The quantum yield is a luminescence property that is related to lifetimes. The luminescence quantum yield (Φ) is the ratio of the number of photons emitted to the number of photons absorbed. Therefore, the maximum value of Φ is 1. In practice, the quantum yield is less than unity for virtually all luminescent materials. The reason is the large number of non-radiative processes that lead to a decrease in the number of emitted photons. The

quantum yield can be defined in terms of the rate constants of the radiative (k_{rad}) and non-radiative (k_{nr}) processes according to eqn [10]:

$$\Phi = \frac{\sum k_{\text{rad}}}{\sum k_{\text{rad}} + \sum k_{\text{nr}}} \quad [10]$$

The k_{rad} term includes the rate of fluorescence and phosphorescence while the k_{nr} term includes the rate constants of all the non-radiative processes described previously. Remembering that $\tau_f = 1/k_f$ and also using eqn [7], one can express the quantum yield of the fluorescence (Φ_f) in terms of the luminescence lifetimes as:

$$\Phi_f = \frac{k_f}{k_f + \sum k_{\text{nr}}} = \frac{\tau}{\tau_f} \quad [11]$$

A variety of factors are believed to influence the luminescence quantum yields of luminophores.

The Transition Type

Because luminescence is a technique of electronic spectroscopy, the same selection rules apply for luminescence as those that apply for absorption. For organic compounds, the most common luminescence bands are due to $\pi^*-\pi$ and $\pi^*-\sigma$ transitions. The $\sigma^*-\sigma$ transitions, although strongly allowed, are not normally seen because of their high energies in most organic compounds. The spin selection rules also apply. Consequently, fluorescence in most luminescent organic compounds is much stronger than phosphorescence (see the example in the section on organic luminophores). For inorganic compounds, the luminescence transitions may involve the energy levels of the ligands (intra-ligand transitions), the metal ions (d-d transitions), or both the metal and the ligand (charge transfer transitions). Intra-ligand transitions are similar to the transitions discussed above for organic compounds. The d-d transitions are usually forbidden transitions, so the corresponding absorption and emission bands are generally weak. Charge transfer transitions are strongly allowed and can occur either from the ligand orbitals to the metal orbitals (ligand-to-metal charge transfer, LMCT) or vice versa (metal-to-ligand charge transfer, MLCT).

Structural Rigidity

Molecules that have *rigid* structures normally exhibit strong luminescence. Three examples are shown in **Scheme 1**. In each pair the fluorophore on the left has the more rigid structure, resulting in greater luminescence quantum yield. Note in the third example that the stronger luminescence intensity is due to the complexation with a metal ion (i.e. the complex is more rigid than the free ligand). The higher luminescence quantum yields for *rigid* luminophores are

probably due to the inhibition of the internal conversion rates and vibrational motion in these compounds.

Substitution

The nature of the substituents on, say, an aromatic ring may increase or decrease the quantum yield. For example, halogen and ketone substituents on anthracene generally decrease the fluorescence quantum yield. In contrast, the quantum yield of diphenyl anthracene is nearly unity (compared with $\Phi_f = 0.4$ for unsubstituted anthracene). Phosphorescence becomes an important factor if the substituents contain heavy atoms (for example halogens). In this case the reduction in fluorescence is accompanied by an increase in phosphorescence. This effect (called the *heavy atom effect*) is specially important in inorganic luminophores because of the involvement of the metal ions. The strong spin-orbit coupling in metal ions leads to the relaxation of the spin selection rules. Therefore, most inorganic luminophores exhibit strong phosphorescence (see below).

Other Factors

Many other factors affect luminescence quantum yields. Among these factors are temperature, solvent, phase and pH. A reduction in temperature suppresses non-radiative processes and thus increases Φ . This is why it is common to run luminescence experiments at cryogenic temperatures. The solvent is involved in many non-radiative processes. An increase in the viscosity of the solvent generally decreases the rate of non-radiative de-excitation. Also, the stretching frequency of the bonds of the

Scheme 1

solvent molecules is an important factor. For example, one of the common procedures to increase the quantum yield is to run the luminescence measurements in deuterated solvents (e.g. D₂O instead of H₂O). The quenching caused by the solvent may be removed by running the luminescence measurements in the solid state instead of solutions (examples are given later). Finally, a change in pH may strongly alter the Φ value because the structure of many luminophores may be different in acidic and basic media.

Case Studies for Photoluminescence

Organic Luminophores

The luminescence properties of anthracene and its derivatives provide an excellent illustration of the relation between the excited state distortion and the profile of the luminescence spectra. **Figure 6** shows the luminescence and absorption spectra of anthracene. Note that the

extinction coefficient for the singlet–singlet transition is 8 orders of magnitude higher than the value for the singlet–triplet transition. This observation suggests that the absorption and emission bands in the region with $\lambda < 500$ nm are due to a spin-allowed transition (singlet $\leftrightarrow$ singlet), hence the emission in this region is due to fluorescence. On the other hand, the bands in the region with $\lambda > 500$ nm are due to a spin-forbidden transition (singlet $\leftrightarrow$ triplet), hence the emission in this region is due to phosphorescence.

Figure 6 shows that the mirror image rule applies very well to the absorption and fluorescence bands of the $S_0 \leftrightarrow S_1$ transition. Note that among the vibronic bands, the 0–0 and 0–1 transitions have the strongest intensities. These observations suggest that the excited state distortion is very small in anthracene. **Figure 6** also shows that there is correlation even between the absorption and phosphorescence characteristic of the $S_0 \leftrightarrow T_1$ transition. However, the mirror image rule does not apply as strongly as it does for the $S_0 \leftrightarrow S_1$ transition. For

Figure 6 Emission (solid line) and absorption (dashed line) spectra of anthracene in solution. The assignments of the vibronic transitions are shown in the bottom portion of the figure. Reproduced with permission from Turro NJ (1978) *Modern Molecular Photochemistry*, p. 94. Menlo Park: Benjamin/Cummings.

Figure 7 Emission (right) and absorption (left) spectra of 9-anthramide in tetrahydrofuran. Reproduced with permission from Shon RS-L, Cowan DO, and Schmiel WW (1975) Photodimerization of 9-anthroate esters and 9-anthramide. *The Journal of Physical Chemistry* 79: 2087–2092.

example, the intensity is greater for the 0–1 transition than for the 0–2 transition in the phosphorescence band, but the opposite trend is seen in the corresponding absorption band. Moreover, while the absorption and emission peaks are nearly superimposed for the 0–0 vibronic peak of the $S_0 \leftrightarrow S_1$ transition, there is a greater separation between the corresponding peaks characteristic of the $S_0 \leftrightarrow T_1$ transition. These observations are consistent with the excited state distortion for the triplet excited state (T_1) being greater than the distortion of the singlet excited state (S_1).

Substitution of hydrogen atoms of anthracene may lead to a geometry change in the excited state. The extent of this change can be probed by luminescence spectroscopy. **Figures 7 and 8** provide an illustration. In **Figure 7**, the absorption and fluorescence spectra are shown for 9-anthramide. Similar geometries of the ground state and the fluorescent excited state of 9-anthramide are illustrated by (i) the applicability of the mirror image rule, (ii) the peaks characteristic of the 0–0 and 0–1 transitions both being strong, and (iii) the absorption and emission peaks being superimposed for the 0–0 transition. The situation is not the same when the substituent on anthracene is changed from an amide group to an ester group. **Figure 8** shows the absorption and emission spectra of cyclohexyl-9-anthroate. Note that the emission spectrum of cyclohexyl-9-anthroate is structureless and the mirror image rule is lost. Also note the large values of the Stokes shift ($\sim 6000 \text{ cm}^{-1}$) and fwhm ($\sim 5000 \text{ cm}^{-1}$). These observations suggest a largely displaced excited state for cyclohexyl-9-anthroate from the ground state geometry of the molecule. In conclusion, **Figures 7 and 8** show that the luminescent excited state is much more distorted for the ester derivative of anthracene (cyclohexyl-9-anthroate) than for the amide derivative of the same molecule (9-anthramide). One can therefore predict that the ester has a greater tendency to undergo photochemical reactions than the amide.

Inorganic Luminophores

The compound $\text{BaPd}(\text{CN})_4 \cdot 4\text{H}_2\text{O}$ provides an excellent example for the differentiation between fluorescence and phosphorescence based on lifetimes and other luminescence properties. Inorganic compounds that exhibit chain structures show interesting luminescence properties in the solid state. The X-ray structure of $\text{BaPd}(\text{CN})_4 \cdot 4\text{H}_2\text{O}$ consists of $[\text{Pd}(\text{CN})_4]^{2-}$ square-planar ions stacked in one-dimensional chains with an intra-chain Pd–Pd distance of $3.37 \text{ \AA}$ at room temperature. **Figure 9** shows the luminescence spectrum of $\text{BaPd}(\text{CN})_4 \cdot 4\text{H}_2\text{O}$ at 7 K using a nitrogen pulsed laser for excitation. Two emission bands are observed at $\sim 19 \times 10^3$ and $26 \times 10^3 \text{ cm}^{-1}$ (~ 512 and 382 nm , respectively). These bands are designated the *lower energy* (LE) and the *higher energy* (HE) bands, respectively. In **Figure 10** the lifetime of the LE band is plotted versus temperature. A linear fit is obtained. From the resulting equation, the lifetime at 0 K is estimated to be $\sim 2.5 \text{ ms}$ and decreases by approximately a factor of 2 for each 30 K temperature rise. The shorter lifetimes at higher temperatures are due to the larger values of k_{nr} at higher temperatures (eqn [7]). In contrast, the HE band has a lifetime shorter than the instrumental resolution of 10 ns. Thus, the lifetime data suggest that the HE band is fluorescence while the LE band is phosphorescence.

Polarized light can be used to study the luminescence bands for $\text{BaPd}(\text{CN})_4 \cdot 4\text{H}_2\text{O}$. The HE band has polarized emission with the phase of polarization of the fluorescence perpendicular to the $\text{Pd}(\text{CN})_4^{2-}$ square planar plane (z -direction). In contrast, the LE band has polarized emission with the phase of the polarized light the same as the $\text{Pd}(\text{CN})_4^{2-}$ molecular plane (xy -direction). The metal ions in one-dimensional chained compounds are oriented along one particular direction in crystals of layered compounds (along the xy -direction in $\text{BaPd}(\text{CN})_4 \cdot 4\text{H}_2\text{O}$). The absorption band of $\text{BaPd}(\text{CN})_4 \cdot 4\text{H}_2\text{O}$ solid is polarized along the xy -direction. The fact that the HE emission band has the same polarization as the absorption

Figure 10 Lifetime of the $19 \times 10^3 \text{ cm}^{-1}$ luminescence band of $\text{BaPd}(\text{CN})_4 \cdot 4\text{H}_2\text{O}$ versus temperature. The dashed line is extrapolation to higher temperatures. Reproduced with permission from Ellenson WD, Viswanath AK, and Patterson HH (1981) Laser-excited luminescence study of the chain compound $\text{BaPd}(\text{CN})_4 \cdot 4\text{H}_2\text{O}$. *Inorganic Chemistry* 20: 780–783.

band provides further evidence that the HE band is fluorescence. This is because fluorescence takes place immediately after absorption ($\tau < 10 \text{ ns}$) and from the same singlet excited electronic state as the one which absorption populates. In contrast, the LE band occurs from a triplet excited state long after absorption ($\tau = 2.5 \text{ ms}$). Because the absorption and the LE emission bands have different excited states, these bands have different polarization. In accordance with the polarization of the HE band along the same direction as the Pd chains, the

emission maximum of the HE band undergoes a progressive red shift (longer wavelength, lower energy) as the temperature is decreased. The red shift occurs because cooling leads to a thermal contraction of the intra-chain Pd–Pd distance, which results in a smaller HOMO–LUMO energy gap (HOMO = highest occupied molecular orbital, LUMO = lowest unoccupied molecular orbital). In contrast, the position of the LE band is independent of temperature because this band is not polarized along the Pd chains.

The preceding results can be compared with the selection rules for all the possible electronic transitions obtained from group theory, to give electronic assignments (term symbols) for each of the luminescence bands. The resulting electronic assignments are $^1\text{A}_{2u}$ and $^3\text{A}_{2u}$ for the HE and LE bands, respectively. A discussion of the concepts of group theory that lead to this assignment is beyond the scope of this article. However, it is enough to note that the term symbols of the HE and LE bands of $\text{BaPd}(\text{CN})_4 \cdot 4\text{H}_2\text{O}$ differ only in the spin multiplicity (superscripts indicate singlet and triplet, respectively). With this in mind, the difference in the excited state distortion between the HE and LE bands can be used to provide further evidence for the band assignment. The lowest energy absorption band of $\text{BaPd}(\text{CN})_4 \cdot 4\text{H}_2\text{O}$ solid has an energy of $\sim 31 \times 10^3 \text{ cm}^{-1}$. This gives a Stokes shift of ~ 5000 and $11\,500 \text{ cm}^{-1}$ for the HE and LE bands, respectively. **Figure 9** shows that the LE band is much broader than the HE band. The fwhm values of the HE and LE bands are 900 and 3300 cm^{-1} , respectively. The higher values of the Stokes shift and fwhm for the LE band are consistent with the assignment that the LE band is phosphorescence while the HE band is fluorescence of the same electronic transition. This is the case because the excited state distortion of phosphorescence is greater than that of the fluorescence of the same electronic transition (with a different spin state). The Jablonski diagram shown in **Figure 1** illustrates the higher Stokes shift for phosphorescence compared with fluorescence.

In summary, the HE and LE luminescence bands of $\text{BaPd}(\text{CN})_4 \cdot 4\text{H}_2\text{O}$ are assigned as fluorescence and phosphorescence, respectively. The basis of this assignment is the difference between the two bands in the lifetime values, polarization character, temperature dependence, and excited state distortion (Stokes shift and fwhm values).

Finally, an interesting aspect of the luminescence spectrum of $\text{BaPd}(\text{CN})_4 \cdot 4\text{H}_2\text{O}$ is the strong phosphorescence intensity (compared with the relative phosphorescence/fluorescence intensity of anthracene). This is a direct consequence of the strong spin–orbit coupling of palladium. This provides an illustration of the heavy atom effect which is generally more important in inorganic luminophores relative to their organic counterparts.

Quenching of Emission

Theory

In luminescence spectroscopy, quenching refers to any process that leads to a reduction in the luminescence intensity of the luminophore. Static and dynamic quenching are the most common types of luminescence quenching and will be described in the following sections. A third type of quenching also exists, namely 'inner-filter quenching'. An inner-filter effect occurs when the total absorbance of the solution is high (greater than 0.1 au). This leads to a reduction in the intensity of the excitation radiation over the path length. Quenching of this type is not generally categorized among the major quenching process because it is a trivial type of quenching that is not really involved in the radiative and non-radiative transitions in luminescence spectroscopy.

Both static and dynamic quenching require contact of the luminophore with a quencher molecule. This requirement is the basis of the many applications of luminescence quenching. Because there are so many molecules that can act as luminescence quenchers, an appropriate quencher can be selected for any luminophore under study in order to investigate specific properties of the luminophore. An example of biochemical applications of luminescence quenching is given later in this section.

Static Quenching

Static quenching occurs upon the complexation of the luminophore (L) with a quencher (Q):

The total concentration of the luminophore, $[L]_0$, is given by:

$$[L]_0 = [L] + [L - Q] \quad [13]$$

The dependence of the luminescence intensity on the quencher concentration can be derived by considering the association constant for the formation of the L-Q complex, K_s :

$$K_s = \frac{[L - Q]}{[L][Q]} = \frac{[L]_0 - [L]}{[L][Q]} \quad [14]$$

Rearrangement gives:

$$\frac{[L]_0}{[L]} = 1 + K_s[Q] \quad [15]$$

Static quenching occurs because the resulting ground state complex is not luminescent and, therefore, the concentration of free L decreases upon its complexation. The ratio $[L]_0/[L]$ is a measure of the decrease of the luminescence intensity due to static quenching. In the

absence of the quencher (Q), the luminescence intensity, I_0 , is highest because $[L]_0 = [L]$. In the presence of Q, the luminescence intensity, I , decreases due to static quenching. Therefore, the ratio $[L]_0/[L]$ is the same as I_0/I . Substituting in eqn [15] gives the Stern-Volmer equation:

$$I_0/I = 1 + K_s[Q] \quad [16]$$

A Stern-Volmer plot of I_0/I against $[Q]$ should give a straight line with a slope equal to K_s , which is also known as the Stern-Volmer constant for static quenching.

Dynamic Quenching (Collisional Quenching)

Dynamic or collisional quenching occurs when the lifetime of the fluorophore is reduced, thus reducing the luminescence quantum yield. The mechanism of this type of quenching involves a collision of the excited luminophore molecule (*L) with a quencher molecule (Q). As a result, *L returns to its ground state without emitting photons and the excitation energy is transferred to Q. The transfer of the excitation energy to Q leads to a reduction of the excited state lifetime of *L and, therefore, a reduction of the luminescence intensity. It can be shown that the reduction of the luminescence intensity due to dynamic quenching is the same as the corresponding reduction of the excited state lifetime:

$$I_0/I = \tau_0/\tau \quad [17]$$

where τ_0 and τ refer to the lifetimes in the absence and presence of the quencher, respectively. The Stern-Volmer equation that governs dynamic quenching can be derived on the basis of the kinetic model shown in **Figure 11**.

The radiative decay rate (k_{rad}) is the reciprocal of the excited state lifetime in the absence of the quencher ($1/\tau_0$). The rates of depopulation of *L in the absence and presence of Q are given in eqns [18] and [19],

Figure 11 Kinetic model for dynamic quenching. In the notation used w , k_{rad} and k_Q refer to the absorption rate, radiative rate and quenching rate, respectively.

respectively:

$$d[{}^*L]/dt = w - k_{\text{rad}}[{}^*L]_0 = 0 \quad [18]$$

$$d[{}^*L]/dt = w - k_{\text{rad}}[{}^*L] - k_Q[{}^*L][Q] = 0 \quad [19]$$

Substituting $(1/\tau_0)$ for K_{rad} , after rearrangement, gives eqn [20], which is the Stern–Volmer equation for dynamic quenching:

$$I_0/I = 1 + K_Q \tau_0 [Q] \quad [20]$$

The term $(k_Q \tau_0)$ is the Stern–Volmer quenching constant for dynamic quenching, K_D . Therefore, the Stern–Volmer equation for dynamic quenching can be re-written as:

$$I_0/I = 1 + K_D [Q] \quad [21]$$

Note that eqns [16] and [21] are identical in form, and from both equations Stern–Volmer plots can be made in order to obtain the constants K_S and K_D , respectively. This can be carried out simply by measurements of the luminescence intensity in the presence and absence of the quencher. However, such a study does not distinguish between the two mechanisms. The easiest and most definitive way to determine the quenching mechanism is to carry out a study of the lifetimes in the presence and absence of the quencher. The excited state lifetime decreases in the presence of quencher if dynamic quenching is the mechanism involved. Note that according to eqn [17], a Stern–Volmer plot can be obtained by plotting (τ_0/τ) on the y -axis instead of I_0/I :

$$\tau_0/\tau = 1 + K_D [Q] \quad [22]$$

In contrast, the excited state lifetime is invariant in the presence of the quencher if static quenching is the mechanism involved. Therefore, plotting (τ_0/τ) versus $[Q]$ will simply yield a horizontal line parallel to the x -axis ($y = 1$).

Example

Tryptophan residues in a protein luminesce strongly whether they are on the surface of the protein or in its interior. When a quenching experiment is carried out with ionic quenchers, such as the iodide ion, the resulting quenching involves only surface-localized tryptophan residues. On the other hand, non-ionic quenchers, such as acrylamide, are able to penetrate into the interior of the protein and provide quenching constants that are really average constants and give information about both surface and interior tryptophan residues.

One way of separating the fluorescence quenching parameters associated with external and internal fluorophores is to use a double-quenching method in which two

Figure 12 A Stern–Volmer plot for the fluorescence quenching of HDL₁ (solid lines) and HDL₂ (dashed lines). The different legends refer to samples obtained from rats fed with manganese-adequate ($\diamond$) and manganese-deficient ($\square$) diet. The fluorescence was monitored at 338 nm ($\lambda_{\text{exc}} = 295$ nm) characteristic of tryptophan residues. Reproduced with permission from Taylor PN, Patterson HH, and Klimis-Tavatzis DJ (1997) A fluorescence double-quenching study of native lipoproteins in an animal model of manganese deficiency. *Biological Trace Element Research* 60: 69–80.

quenchers are applied simultaneously. The first quencher is used to selectively quench the fluorescence emission of exposed fluorophores. On the other hand, the second quencher is used to quench the fluorescence emission of both surface and interior fluorophores non-selectively.

Figure 12 shows Stern–Volmer plots of two samples of high density lipoproteins, HDL₁ and HDL₂ (referring to different densities of high density lipoproteins). These samples were obtained from rats raised on diets containing different amounts of the element manganese. A linear plot was obtained only for the manganese-deficient sample of HDL₂. From the equation of the straight line for this sample, the Stern–Volmer constant was determined as 0.88 M^{-1} . The plots were non-linear for the other samples, indicating the presence of more than one class of fluorophores, which are unequally accessible to the charged I^- quencher. In **Figure 13**, the fluorescence quenching of HDL₁ by iodide in the presence of various amounts of the non-ionic quencher acrylamide are shown using a modified Stern–Volmer method. The plots are all linear and provide fluorescence quenching parameters characteristic of interior and surface-exposed residues. **Table 1** shows a listing of the quenching constants for the different samples.

A statistical analysis of the parameters in **Table 1** indicates that the acrylamide quenching constant for exposed fluorophores is significantly different in manganese-adequate HDL₁ compared with manganese-deficient HDL₁. In manganese-adequate HDL₂, there were two populations of fluorophores accessible to acrylamide, whereas in manganese-deficient HDL₂, all fluorophores were accessible to both quenchers. It was concluded based on these results that the local environments of the external fluorophores have different structures and charge distribution in manganese-adequate HDL₁ versus

Figure 13 A modified Stern–Volmer plot for the fluorescence quenching of HDL₁ by iodide in the presence of varying amounts of acrylamide. The data are shown for HDL₁ samples obtained from rats fed with manganese-deficient (top) and manganese-adequate (bottom) diet. The fluorescence was monitored at 338 nm ($I_{\text{exc}} = 295$ nm) characteristic of tryptophan residues. Table 1 Quenching constants for tryptophan residues in different high-density lipoprotein samples

Quenching constant/ M^{-1}	Lipoprotein			
	HDL ₁		HDL ₂	
	MnA	MnD	MnA	MnD
K_i	9.14 ± 0.44	17.18 ± 7.72	4.63 ± 0.00	0.88 ± 0.00
K_{A1}	5.21 ± 0.88	6.15 ± 1.50	1.61 ± 0.50	–
K_{A2}	4.27 ± 0.11	5.96 ± 0.05	1.51 ± 0.00	–

MnA, manganese-adequate sample; MnD, manganese-deficient sample; K_i , iodide quenching constant; K_{A1} and K_{A2} , acrylamide quenching constant for exposed and partly exposed fluorophores, respectively.

manganese-deficient HDL₁. For HDL₂ samples, it was concluded that one-third of the fluorophores were accessible to iodide and all external and internal fluorophores were accessible to acrylamide in manganese-adequate samples, whereas in manganese-deficient samples, all fluorophores were accessible to both quenchers.

Energy Transfer

Theory

Energy transfer refers to a process in which an excited atom or molecule (*donor*) transfers its excitation energy to an *acceptor* atom or molecule during the lifetime of the

donor excited state. **Figure 14** shows that as a result of energy transfer, the donor returns to its ground state while the acceptor is promoted to its excited state. If the acceptor is a luminescent species, it can emit by virtue of energy transfer, that is the acceptor luminesces as a result of the excitation of the donor. Such a luminescence is called ‘sensitized luminescence’, and some textbooks use the terms ‘sensitizer’ and ‘activator’ instead of ‘donor’ and ‘acceptor’. Many applications in chemistry, physics, materials science and biochemistry are based on sensitized luminescence. A later section provides an example of the application of energy transfer processes in biological systems. Energy transfer processes occur via radiative or non-radiative mechanisms.

Radiative Mechanisms

This mechanism involves the absorption of light by a donor atom or molecule (D) followed by emission of a photon by the donor and the absorption of the emitted photon by another molecule called the acceptor (A). The process can be represented as follows:

The radiative mechanism is important if the acceptor A absorbs at the wavelength at which the donor emits. The efficiency of the process is determined simply by the quantum yield of the donor luminescence and the absorbance of the acceptor at the donor emission wavelength. No significant interaction between A and D is required in this mechanism and, therefore, radiative energy transfer can occur over extremely large separations of D and A. The radiative mechanism is not important if A and D are similar molecules because of the usually small overlap of the emission and absorption spectra in this case.

Non-Radiative Mechanisms

The radiative mechanism is a trivial case of energy transfer because it can be characterized by measuring the donor absorption and the acceptor emission separately from each other. In fact, most textbooks refer to the radiative pathway as a ‘trivial mechanism’ for energy transfer and do not really consider it as an energy transfer mechanism. Note in **Figure 14** that the donor does not emit light. Instead, the excitation energy is transferred non-radiatively to the acceptor. The non-radiative pathway shown in **Figure 14** is the mechanism that is typically used in most textbooks to represent energy transfer processes. Non-radiative energy transfer processes occur via two major mechanisms, the *Förster resonance mechanism* and the *Dexter exchange mechanism*.

Figure 14 Energy transfer from a donor (D) to an acceptor (A).

The *Förster resonance mechanism* involves an electrostatic interaction between D and A. Such an interaction can occur over a long range, that is it does not require a very short contact between the donor and the acceptor. Energy transfer via the resonance mechanism may proceed over donor–acceptor distances as long as 50–100 Å. In order for energy transfer to be efficient via the resonance mechanism, the energies of the donor and acceptor transitions $D^* \rightarrow D$ and $A \rightarrow A^*$ must be nearly identical (hence the name ‘*resonance mechanism*’). Nevertheless, the presence of phonons (vibrational quanta) may provide assistance for energy transfer when small differences exist between the donor and the acceptor excited states. Such processes are called *phonon-assisted* energy transfer processes (Figure 15). The energies of the phonons should be high enough to surmount the difference between the donor and acceptor excited states. However, too high phonon energies increase the likelihood of non-radiative de-excitation (see above), which would take place before energy transfer can take place.

The *Dexter exchange mechanism* involves a direct contact between the donor and the acceptor atoms or molecules. The exchange interaction between the donor D and the acceptor A involves a transition state with a D–A distance that is close to the sum of the gas-kinetic collision radii of D and A, respectively. Therefore, information about the energy transfer mechanism can be gained by structural studies of the system under consideration. If the D–A distance is short (normally < 5 Å) then the exchange mechanism is the more likely, but if the D–A distance is long ($\gg 5$ Å) then the resonance mechanism would be more likely.

The energy transfer efficiency is strongly dependent on the spectral overlap between the donor emission and the acceptor absorption. This is valid for both exchange and resonance mechanisms, as shown in the following expression for the energy transfer rate:

$$k_{ET} = f(r_{D-A}) \int I_D \epsilon_A d\bar{\nu} \quad [26]$$

Figure 15 Phonon-assisted energy transfer. The energy difference between the excited states of D and A is provided by phonons.

Figure 16 Experimental determination of the donor–acceptor spectral overlap from emission and absorption spectra. Reproduced with permission from Turro NJ (1978) *Modern Molecular Photochemistry*, p. 299. Menlo Park: Benjamin/Cummings.

where the integral represents the spectral overlap between the donor emission I_D and the acceptor absorption ϵ_A . The factor $f(r_{D-A})$ is a function of the intermolecular distance between the donor and acceptor centres (r_{D-A}) and is governed by the relevant energy transfer mechanism (Förster or Dexter mechanism). The donor–acceptor spectral overlap can be determined experimentally by spectroscopic measurements, as illustrated in Figure 16.

Example

Trivalent lanthanide ions, Ln(III), can be substituted for certain metal ions in proteins to gain structural information about the sites of these metals. The ability of Ln(III) ions to substitute for metal ions such as Ca(II), Zn(II), and Mn(II) in proteins stems from the similarity between Ln(III) and these ions in ionic radii, coordination

numbers (6–9) and preference to oxygen donor ligands. The higher charge density of Ln(III) makes these ions substitute with higher affinity than the metal ions in many metal-binding proteins. The quantum yield of luminescence is low for free Ln(III) but increases upon binding in close proximity to an aromatic amino acid within the protein: phenylalanine (Phe), tyrosine (Tyr) or tryptophan (Trp). When the protein is irradiated with wavelengths that correspond to the absorption maxima of these amino acids (~250–300 nm), the luminescence bands of the bound Ln(III) are enhanced by energy transfer. The strong sensitized luminescence of the Ln(III) makes these ions act as ‘probes’ of detailed and accurate structural information about the metal-binding sites in the proteins studied, as illustrated in the following example.

The protein α -lactalbumin is involved in the regulation of lactose synthesis. The binding of bovine α -lactalbumin (BLA) to Ca(II) is very strong ($\log K = 8$ –9). Eu(III) can bind apo-BLA (apo: metal-free) in the Ca(II) binding site. The appearance of sensitized luminescence for Eu(III) is illustrated in **Figure 17**. Note that owing to energy transfer, the luminescence intensity of BLA-bound Eu(III) (upper curve) is much stronger than the intensity of free Eu(III) (lower curve). **Figure 17** shows that the increase in the intensity of the $^5D_0 \rightarrow ^7F_2$ transition is most drastic when the ratio (R) of [Eu(III)]/[BLA] is between 1 and 2, and the intensity continues to increase when $R > 2$. This is an indication of the binding of at least two Eu(III) ions to BLA. The Eu(III) luminescence is recorded in **Figure 17** for the $^5D_0 \rightarrow ^7F_2$ hypersensitive transition. A hypersensitive transition is a transition whose intensity is extremely sensitive to changes in the environment of the Ln(III) ion. Hypersensitivity is exhibited because of the $\Delta J = 2$ quadrupolar

Figure 17 Luminescence titration of apo- α -lactalbumin (BLA) with europium chloride in D_2O . The luminescence intensity is monitored for the $^5D_0 \rightarrow ^7F_2$ emission line of Eu(III) with $\lambda_{exc} = 395$ nm. The upper curve shows the data for BLA-bound Eu(III) and the lower curve shows the data for $EuCl_3$ alone. Reproduced with permission from Bünzli JCG and Choppin GR (1989) *Lanthanide Probes in Life, Chemical and Earth Sciences*, p. 279. Amsterdam: Elsevier.

nature of the transition. The importance of this transition in the BLA-bound Eu(III) is illustrated in **Figure 18**. The excitation spectra of the Eu(III)-bound BLA are shown in **Figure 18** monitoring the $^5D_0 \rightarrow ^7F_0$ emission. The excitation spectra are resolved into several components, especially for R values > 1 . The appearance of bands I and II indicates the presence of two different binding sites for Eu(III) in BLA. Band III is due to non-bonded (solvated) Eu(III) ions. Therefore, it is concluded that Eu(III) ions displace Ca(II) ions from BLA and bind into two sites.

Besides the determination of the number of metal binding sites, luminescence studies of Ln(III) ions in biological systems allow the determination of other structural properties of proteins such as the number of bonded water molecules, the sum of ligand formal charges and the site symmetry of the metal ion sites. For example, lifetime measurements in H_2O/D_2O mixtures allow the determination of the number of water molecules (n) that are coordinated to the metal ions in the different binding sites:

$$n = 1.05[1/\tau(H_2O) - 1/\tau(D_2O)] \quad [27]$$

In the preceding example, the numbers of coordinated water molecules in sites I and II were determined as 2 and 4, respectively.

Excimers and Exciplexes

Theory

Excimers and exciplexes are excited state complexes. An excited state dimer is called an *excimer*. Excimer formation can be represented by the following equation:

where the asterisks refer to species in their excited states. According to eqn [28], an excimer is formed when an excited molecule interacts with another identical ground state molecule. As a result of this interaction, an actual bond forms between the two monomer atoms in the excited state. Excited state interactions are not limited to the formation of homonuclear diatomic complexes. If interaction occurs between an excited molecule of one type and a ground state molecule of a different type, the resulting excited state complex is called an *exciplex*:

An exciplex can also form if more than two atoms are involved in the excited-state bond, whether these atoms are identical or different. Therefore, we can write a general equation to represent exciplex formation:

Figure 18 Curve-resolved Eu(III) excitation spectra of apo-BLA in D₂O. R represents the [Eu(III)]/[BLA] ratio. Reproduced with permission from Bünzli JCG and Choppin GR (1989) *Lanthanide Probes in Life, Chemical and Earth Sciences*, p. 280. Amsterdam: Elsevier.

From eqn [30], it is clear that an excimer is a special kind of exciplex where $A = B$ and $n = m = 1$, so it is more appropriate to use the term *exciplex* when referring to excited state complexes in general, including both homoatomic and heteroatomic species.

It is important to recognize that exciplex formation is a physical phenomenon and not a chemical one. That is, bonding between the molecules only lasts as long as the excited state lifetime of the molecule, and the exciplex bond dissociates upon radiative or non-radiative de-excitation. Nevertheless, there are cases in which exciplex formation leads to photochemical reactions. For example, exciplexes are believed to be the reactive intermediates in the photochemical pathway of the Diels–Alder cycloaddition reactions of unsaturated organic compounds. Since photoluminescence is a photophysical process, the focus here will be on the photophysical aspect of exciplex formation instead of the photochemical reactions that result from exciplex formation.

Example of an Organic Exciplex

The characteristics of exciplex emission can be understood from potential energy diagrams of exciplex-forming species. **Figure 19** illustrates the spectroscopic features of exciplexes in relation to the potential surfaces of the ground and the excited electronic states. The spectra and potential surfaces are shown for pyrene, the classical example for excimer emission in organic compounds. According to **Figure 19**, the ground state is repulsive (no potential well) and the excited state is strongly bonding (deep potential well) along the pyrene–pyrene internuclear distance. This explains why the excimer bond forms only in the excited state.

Organic exciplexes are best identified by studying the variation of their emission spectra with concentration. This is illustrated in **Figure 19** for pyrene (py). At low

Figure 19 Excimer emission of pyrene. The upper curves show the potential surfaces of the ground and the luminescent excited electronic state. Reproduced with permission from Turro NJ (1978) *Modern Molecular Photochemistry*, p. 141. Menlo Park: Benjamin/Cummings.

pyrene concentrations ($\leq 10^{-5}$ M), the major luminescence band is due to the monomer. The characteristics of the monomer emission include: (i) vibronic structure is present, and (ii) the emission profile is independent of concentration at concentrations $\leq 10^{-5}$ M. As the pyrene concentration is increased above 10^{-5} M, the monomer emission is quenched and a new lower-energy emission band appears due to the formation of

a $^*[\text{py-py}]$ excimer. The intensity of the excimer band increases with a concentration increase. The characteristics of the excimer emission band of pyrene in **Figure 19** are: (i) it is a structureless band with no vibronic structure, (ii) it has a lower energy than the monomer emission band and (iii) its intensity increases relative to the monomer emission band as the concentration is increased above a critical value (10^{-5} M for pyrene). These characteristics of the pyrene excimer bands are valid for the emission bands of organic exciplexes in general.

Examples of Inorganic Exciplexes

The formation of inorganic exciplexes has attracted attention only relatively recently. Exciplexes formed in coordination compounds could be either *ligand-centred exciplexes* or *metal-centred exciplexes*. Ligand-centred exciplexes are normally formed from coordinatively saturated complexes (where the metal ion has a high coordination number with no 'vacant' sites) and another species. In this situation, excitation of a ligand in the complex may result in the formation of an exciplex bond between the ligand and another molecule that exists in the solution (such as a solvent molecule). Metal-centred exciplexes, on the other hand, are normally formed from coordinatively unsaturated complexes and another species. In coordinatively unsaturated complexes, the potential coordination site(s) present in the metal ion can be filled by neutral electron-donor species (Lewis bases), anions or another metal ion. The latter type gives rise to the formation of *metal-metal bonded exciplexes*. This class of inorganic exciplexes is rather interesting because thus far all reported examples are luminescent.

The formation of the silver-silver bonded exciplexes $^*[\text{Ag}(\text{CN})_2]_n$ ($n \geq 2$) will serve as an illustration. The formation of these exciplexes in the solid state has been reported by the authors of this article. The $[\text{Ag}(\text{CN})_2]^-$ complex ion is a good candidate for the formation of metal-metal bonded exciplexes because its low coordination number (2) implies that several potential coordination sites are available.

Single crystals have been grown from a saturated solution of KCl that contains small amounts of $\text{K}[\text{Ag}(\text{CN})_2]$. The crystals harvested from this solution are called $[\text{Ag}(\text{CN})_2^-]/\text{KCl}$ doped crystals, that is, $[\text{Ag}(\text{CN})_2]^-$ guest ions are incorporated into (or doped in) the KCl host lattice. In these doped crystals, the Ag^+ and CN^- ions replace the K^+ and Cl^- ions, respectively, in some sites in the KCl lattice. Infrared measurements of single crystals of $[\text{Ag}(\text{CN})_2^-]/\text{KCl}$ have shown that multiple peaks exist in the $\nu_{\text{C-N}}$ region, indicating the presence of several local environments for the $[\text{Ag}(\text{CN})_2]^-$ ions within the KCl lattice. This result has been explained in terms of the

presence of monomers, dimers, trimers, etc. of $[\text{Ag}(\text{CN})_2]^-$ in the doped crystal.

The luminescence spectra of $[\text{Ag}(\text{CN})_2^-]/\text{KCl}$ doped crystals at 77 K are shown in **Figure 20**. It is interesting to note that at least four emission bands appear in the luminescence spectra of a single crystal of $[\text{Ag}(\text{CN})_2^-]/\text{KCl}$. The most prominent bands are labelled as A, B, C and D in **Figure 20**. This observation is consistent with the conclusion based on the infrared spectra that the $[\text{Ag}(\text{CN})_2]^-$ ions exist as monomers, dimers, trimers, etc in the KCl lattice. Therefore, $[\text{Ag}(\text{CN})_2^-]_n$ oligomer ions in the KCl lattice with different values of n are responsible for the different luminescence bands. The strong dependence of the emission spectra on the excitation wavelength is unusual because emission spectra of luminescent materials are usually independent of the excitation wavelength. By controlling the excitation wavelength, a specific $[\text{Ag}(\text{CN})_2^-]_n$ oligomer can be excited independently from the other oligomers so that the luminescence occurs primarily from this excited oligomer. That is, different $[\text{Ag}(\text{CN})_2^-]_n$ oligomers in

Figure 20 Photoluminescence spectra of $[\text{Ag}(\text{CN})_2^-]/\text{KCl}$ doped crystals at 77K. The letter assignment of the luminescence bands follows the notation used in **Table 2**. Reproduced with permission from Omary MA and Patterson HH (1998) Luminescent homoatomic exciplexes in dicyanoargentate (I) ions doped in alkali halide crystals: 1. Exciplex tuning by site-selective excitation. *Journal of the American Chemical Society* 120: 7696–7705.

the KCl lattice act as independent luminophores, each of which has a characteristic excitation wavelength. The emission is *tuned* to any of the bands A–D by changing the excitation wavelength. This is an interesting optical phenomenon that has been called *exciplex tuning*.

The luminescence bands of $[\text{Ag}(\text{CN})_2^-]/\text{KCl}$ are assigned, as shown in **Table 2**, to $^*[\text{Ag}(\text{CN})_2]_n$ exciplexes that differ in the value of n and in their geometry. The exciplex assignment of these bands is based on both

Table 2 Assignment of the luminescence bands of $[\text{Ag}(\text{CN})_2^-]/\text{KCl}$ doped crystals

Band	$\lambda_{\text{mas}}^{\text{em}}$ nm	$\lambda_{\text{mas}}^{\text{exc}}$ nm	fwhm/ (10^3 cm^{-1})	Assignment
A	285–300	225–250	3.31	$^*[\text{Ag}(\text{CN})_2]_2$ (excimers)
B	310–360	270–390	3.70	Angular $^*[\text{Ag}(\text{CN})_2]_3$ (trimer exciplexes)
C	390–430	250–270	3.05	Linear $^*[\text{Ag}(\text{CN})_2]_3$ (trimer exciplexes)
D	490–530	300–360	4.01	$^*[\text{Ag}(\text{CN})_2]_n$ ($n \geq 5$, de- localized exciplexes) ^a

^aIt is assumed that the stabilization due to Ag–Ag interactions converges in $[\text{Ag}(\text{CN})_2]_n$ oligomers with $n \geq 5$.

experimental and theoretical considerations. The following is an overview of the evidence used for this assignment:

(1) *The energies of the luminescence bands of $[\text{Ag}(\text{CN})_2^-]/\text{KCl}$ are extremely low relative to the absorption bands of dilute solutions of $[\text{Ag}(\text{CN})_2]$ (which represent the $[\text{Ag}(\text{CN})_2^-]$ monomer).*

The absorption spectra of dilute solutions of $[\text{Ag}(\text{CN})_2^-]$ show peak maxima with energies $> 50\,000 \text{ cm}^{-1}$. The excitation and emission maxima are red-shifted by as much as $23\,000$ and $30\,000 \text{ cm}^{-1}$, respectively, from the monomer transition. These large red shifts must be due to the oligomerization of $[\text{Ag}(\text{CN})_2^-]$ units, as suggested by electronic structure calculations (see below).

The fact that the Ag(I) ion has a $4d^{10}$ closed shell electronic configuration forbids the formation of strong Ag–Ag bonds in the ground state. Excited states such as $4d^9 5s^1$, however, do not have a closed shell configuration. Hence, Ag–Ag bonding in the excited state is possible, which leads to the formation of $^*[\text{Ag}(\text{CN})_2]_n$ exciplexes. **Figure 21** depicts the potential surfaces of the ground state and the first excited state of a $[\text{Ag}(\text{CN})_2^-]_2$ dimer, as plotted from electronic structure calculations. The formation of a $^*[\text{Ag}(\text{CN})_2]_2$ excimer is illustrated by the deep potential well in the excited state at a shorter Ag–Ag equilibrium distance than the corresponding ground state distance. The electronic transitions depicted in **Figure 21** explain the low emission and excitation energies (transitions (a) and (b)) relative to the monomer absorption (transition (c)).

Figure 21 Potential energy diagram of the ground and the first excited electronic states of $[\text{Ag}(\text{CN})_2]_2$ (eclipsed configuration) as plotted from extended Hückel calculations. The excimer $[\text{Ag}(\text{CN})_2]_2$ corresponds to the potential minimum of the excited state. The optical transitions shown are (a) excimer emission, (b) solid state excitation and (c) dilute solution absorption. Reproduced with permission from Omary MA and Patterson HH (1998) Luminescent homoatomic exciplexes in dicyanoargentate (I) ions doped in alkali halide crystals: 1. Exciplex tuning by site-selective excitation. *Journal of the American Chemical Society* 120: 7696–7705.

Figure 22 Surfaces of the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) for $[\text{Ag}(\text{CN})_2]_2^-$ (staggered isomer) and $[\text{Ag}(\text{CN})_2]_3^-$ (eclipsed isomer), as plotted from *ab initio* calculations. Note the Ag-Ag antibonding character for the HOMO and the Ag-Ag bonding character for the LUMO in both cases.

(2) *The excited states of $[\text{Ag}(\text{CN})_2]_n^-$ oligomers are largely distorted from their ground states.*

The Stokes shifts for the luminescence bands of $[\text{Ag}(\text{CN})_2^-]/\text{KCl}$ range from 7000 to 15 000 cm^{-1} . The fwhm values are in the 3000–4000 cm^{-1} range (Table 2), which are large values. As explained earlier, large excited state distortions are due to large differences in the bonding properties between the molecular orbitals that represent the ground and excited states, respectively. The ground state of an exciplex is antibonding while its first excited state is bonding. Figure 22 illustrates this fact for the dimer $[\text{Ag}(\text{CN})_2]_2^-$ and the trimer $[\text{Ag}(\text{CN})_2]_3^-$. In both cases, the HOMO has a Ag-Ag antibonding character while the LUMO has a Ag-Ag bonding character. Similar results were obtained for other $[\text{Ag}(\text{CN})_2^-]_n$ oligomers. Photoexcitations from antibonding HOMOs to bonding LUMOs lead to the formation of $^*[\text{Ag}(\text{CN})_2]_n$ exciplexes.

(3) *The luminescence bands are generally lacking in structure.*

Note that all the luminescence bands shown in Figure 20 have no detailed structure. This is a similar feature to exciplex emission in organic compounds, as illustrated in Figure 19 for the excimer band of pyrene. The apparent structure for band B is due to the existence

of two different geometrical isomers of the $[\text{Ag}(\text{CN})_2^-]_3$ trimer, not to vibronic structure. The absence of structured emission was obtained for $[\text{Ag}(\text{CN})_2^-]/\text{KCl}$ even though the luminescence measurements were carried out in the solid state for a doped crystal (1.1 mol% Ag) at cryogenic temperature (77 K). Doping and low temperatures normally reduce the chances of band broadening for luminophores that do not exhibit exciplex emission. Hence, the structureless emission of $[\text{Ag}(\text{CN})_2^-]/\text{KCl}$ must be due to exciplex formation.

Chemiluminescence

When exothermic chemical reactions occur, the product species are usually in their ground electronic states. However, some chemical reactions produce product species in electronically excited states which luminesce. This phenomenon is called *chemiluminescence*. Incidentally, chemiluminescence occurs in a number of biological systems (for example, the firefly), where it is called *bioluminescence*.

A common example of chemiluminescence is the reaction of luminol in basic solution with an oxidizing

agent such as oxygen:

The 3-aminophthalate product ion is in an excited electronic state and shows luminescence in the visible region. Reaction [31] is catalysed by the presence of certain metal ions such as Cr(III) and the intensity of the chemiluminescence has been found to be proportional to the concentration of the specific metal ion, usually in the concentration range of parts per billion (ppb). Thus, the luminol reaction can be used to determine the concentration of selected metal ion species at very low concentrations.

A second common example of chemiluminescence in the gas phase is the reaction of nitric oxide with ozone:

Here, the product species NO_2 is produced in an excited electronic state and emits light in the visible–near IR

region. It has been found that the intensity of the chemiluminescence is proportional to the concentration of NO in the ppm–ppb range. Thus, the reaction shown in eqn [32] can be used as the basis for the development of a chemical sensor for NO. The detection of NO is important because nitric oxide is a chief environmental pollutant, and also because NO plays an important role in human biology.

Introduction

NMR spectroscopy has proved to be a useful technique for studying interactions between proteins and other molecules in solution. Such interactions are important in biological molecular recognition processes and they have particular significance for studies of drug–receptor complexes where the results can assist in rational drug design. This article indicates how the appropriate NMR data can be extracted and analysed to provide information concerning interactions, conformations and dynamic processes within such protein–ligand complexes. For complexes of moderate size (up to 40 kDa), nuclear Overhauser effect spectroscopy (NOESY) measurements can often be used to determine the full three-dimensional structure of the complex, thus providing detailed structural information about the binding site and the conformation of the bound ligand. For larger complexes (typically up to 65 kDa), ligand-induced changes in protein chemical shifts, dynamic properties, amide NH exchange behaviour and protection from signal broadening by paramagnetic agents can all be used effectively to map out the ligand-binding sites on the protein by reporting on the nuclei influenced by ligand binding. In addition, NMR can sometimes be used to detect bound water molecules within the binding site and to monitor changes in water occupancy accompanying ligand binding.

NMR offers some advantages over X-ray crystallography in that it examines the complexes in solution, does not require crystals and provides a convenient method

for defining specific interactions, monitoring changes in dynamic processes associated with these interactions, detecting multiple conformations and identifying ionization states of interacting groups within the protein–ligand complexes. However, unlike X-ray crystallography, NMR can provide full structural determinations only for moderately sized proteins (up to 40 kDa at the present time).

Equilibrium Binding Studies

The starting point for studies of protein–ligand interactions often involves determining the equilibrium binding constants for ligands binding reversibly to the protein. These measurements are sometimes made for a series of complexes where either the ligand or the protein is systematically modified in order to measure changes in the binding resulting from the introduction or removal of particular interactions in the complexes. Such investigations need to be accompanied by structural studies on the complexes to see whether the predicted effects have taken place and whether any major conformational perturbations have occurred in the rest of the system. These structural studies need large quantities of purified protein. For a typical sample size of 0.5 mL, the concentrations required vary from 10 μ M for one dimensional spectra to 2 mM or greater for some multidimensional experiments. Large quantities of $^{13}\text{C}/^{15}\text{N}$ -labelled proteins are usually prepared by cloning the appropriate gene into an over-expressing bacterial cell line and growing the cells using [^{13}C]glucose or [^{15}N]ammonium salts as the sole sources of carbon and nitrogen respectively.

Assignment of Protein and Ligand Signals in the Complex

Fast and Slow Exchange Conditions

Before any detailed structural and dynamic information can be obtained from the NMR spectra of the complexes,

the signals need to be assigned to specific nuclei in the ligand or protein. An important first step is to ascertain whether the bound and free species coexist under conditions of fast or slow exchange on the NMR timescale. For a nucleus with chemical shift frequencies ω_B and ω_F in the bound and free species respectively, separate signals are seen for the bound and free species for the case where the lifetime of the complex is long compared with $(\omega_B - \omega_F)^{-1}$: this is designated as the slow exchange condition. If the lifetime of the complex is short compared with $(\omega_B - \omega_F)^{-1}$, then conditions for fast exchange prevail and one observes a single averaged signal weighted according to the populations and chemical shifts in the bound and free forms. When the lifetime of the complex is of the same order as $(\omega_B - \omega_F)^{-1}$ then intermediate exchange conditions prevail, giving rise to spectra with broad, complex signals that are more difficult to analyse.

It is necessary to find out whether one is dealing with fast or slow exchange before further work can be attempted. The data can then be analysed to give the chemical shifts of the signals from the bound ligand or protein. The line widths of the signals can sometimes provide information about the dissociation rate constants of the complex.

Assignment of Protein Signals

In making the assignments of the protein resonances, it is important to ensure that the protein is fully saturated with the bound ligand. Using multidimensional NMR methods in combination with ^2H -, ^{13}C - and ^{15}N -labelled proteins, it is now possible to obtain almost complete signal assignments for backbone and $\text{C}\beta$ protons in proteins of molecular masses up to about 65 kDa. These resonances, once assigned, can be used to monitor ionization state changes, to characterize conformational mixtures and to provide conformational information from NOE measurements for the various complexes.

Assignment of Ligand Signals

Assigned signals for nuclei in the ligand are particularly important because these nuclei are obviously well placed to provide direct information about the binding site in the complex. It is easy to assign signals from bound ligands in fast exchange with free ligand if the assignments of the free ligand are known simply by following the progressive shift of the ligand signals during the ligand titration. It is more difficult to assign signals of nuclei in very tightly binding ligands ($K_d > 10^8 \text{ M}^{-1}$) that are in very slow exchange with those in the free ligand. The usual method of assigning signals from tightly bound ligands is to examine complexes formed with isotopically labelled analogues (^2H , ^3H , ^{13}C and ^{15}N). Deuterated ligands can sometimes assist in making ^1H assignments

by producing differences between ^1H spectra of complexes formed with deuterated and nondeuterated ligands, since signals from deuterated sites will disappear from the spectra. Complexes formed with ^{13}C - or ^{15}N -labelled ligands can also be examined directly by using ^{13}C or ^{15}N NMR: only the signals from nuclei at the enriched positions are detected, which simplifies their assignment. Protons directly attached to ^{13}C or ^{15}N can be detected using an appropriate editing or filtering pulse sequence. Heteronuclear multiple-quantum (or single-quantum) coherence (HMQC or HSQC) experiments allow the attached protons to be detected selectively and the X nuclei to be detected indirectly. A powerful extension of this approach is the 3D-NOESY-HSQC experiment, which allows selective detection of the NOEs from the ligand protons (attached to ^{15}N or ^{13}C nuclei) to neighbouring protons on the protein. The observed ^1H - ^1H NOESY cross peaks are dispersed over the X-chemical shift frequency range. This considerably simplifies the NOESY spectrum at any particular X-frequency and is particularly useful for studying large complexes where there is extensive signal overlap in the normal NOESY spectra.

Complexes formed using less tightly bound ligands ($K_d < 10^6 \text{ M}^{-1}$) can sometimes have spectra showing separate signals for bound and free species in slow exchange that are exchanging sufficiently rapidly to allow their signals to be connected using transfer of magnetization methods. Since the assignments for the free ligand are usually known, these methods give the assignments for the connected signals from the bound ligand.

Other nuclei can sometimes be used effectively for studying protein-ligand interactions. For example, the tritium (^3H) spectrum of a complex formed with a selectively tritiated ligand shows signals from the ligand only and the chemical shifts of these signals can be directly related to the corresponding protons in the nontritiated ligand. ^{19}F NMR measurements on complexes formed with fluorine-containing ligands or proteins can also provide useful information. Assignments of ^{19}F signals from the ligand are often straightforward, since usually only one or two sites are labelled. The simple spectra are ideal for monitoring multiple conformations and dynamic processes in the complexes. Making ^{19}F signal assignments for fluorine-containing proteins is more difficult, but they can be assigned by comparing ^{19}F spectra from different proteins where each fluorine-containing amino acid residue has been systematically replaced by a different amino acid using site-directed mutagenesis. Complexes formed with ligands containing phosphorus can be examined directly by ^{31}P NMR to provide detailed information about phosphate group ionization states and conformations in the bound state.

Determination of Conformations of Protein-Ligand Complexes

NMR is now able to provide full three-dimensional structures for protein-ligand complexes in solution. The general method involves first making the ^1H resonance assignments, then estimating the interproton distances from NOE measurements and dihedral angles from vicinal coupling constants and related data such as residual dipolar couplings in oriented samples in bicelles, and finally calculating families of structures that are compatible with both these distance and angle constraints and the covalent structure using some optimal fitting method, usually distance geometry-based and/or molecular dynamics simulated annealing-based calculations. Ideally, the structures of the unbound species as well as that of the complex should be determined.

Several workers have reviewed this area, particularly from the perspective of its value in drug design, and there have been many reported studies of ligand-receptor complexes where NMR has provided relevant structural information (see **Table 1**). This present overview will consider only a few examples chosen to illustrate particular aspects of protein-ligand interactions.

Many ligands that are flexible in solution adopt a single conformation when bound to a receptor protein. It is important to know the conformation of the bound ligand since this could provide the basis for designing a more rigid and effective inhibitor. Clearly, such information can be obtained directly once the full three-dimensional structure of the complex has been determined. However, in some cases the bound conformation of the ligand can be determined without determining the full structure of the complex if sufficient intramolecular distance and torsion angle constraints can be measured. Several methods based on measurements of intramolecular NOEs in the bound ligand have been proposed. One of these uses the transferred NOE (TrNOE) technique to provide conformational information about the bound ligand. In this method, cross-relaxation (NOE effect) between two protons in the bound ligand is transferred to the free molecule by chemical exchange between bound and free species. Under conditions of fast exchange, the negative NOEs from the bound state can thus be detected in the averaged signals for free and bound ligand. Transferred NOE effects can be detected in 2D-NOESY spectra and this approach has been used, for example, to obtain a set of intramolecular distance constraints between pairs of ligand protons in the tetrapeptide acetyl-Pro-Ala-Pro-Tyr-NH₂ bound to porcine pancreatic elastase and to determine the conformation of the bound peptide.

Other methods of determining the conformation of a bound ligand and details of its binding site involve using isotopically labelled proteins or ligands to simplify the

NMR spectra. These approaches are particularly useful for studying tightly binding ligands where transferred NOE methods cannot provide any information. In such cases, it is necessary to measure directly the intramolecular NOEs within the bound ligand. The main problem is one of detecting the relevant NOEs in the presence of a large number of overlapping NOE cross-peaks from protons in the protein. There are several elegant techniques for measuring intra- and intermolecular NOEs in protein ligand complexes by isotopically labelling only one of the partners in the complex. One very direct strategy is to measure intramolecular ^1H - ^1H NOEs in unlabelled ligands bound to perdeuterated proteins. Because only the ligand ^1H signals are detected, the 2D-COSY (correlation spectroscopy) and NOESY spectra are relatively simple. This approach has been used to examine cyclosporin A in its complex with perdeuterated cyclophilin. Another

approach is to examine complexes of unlabelled protein with $^{13}\text{C}/^{15}\text{N}$ -labelled ligands using NMR isotope-editing procedures that selectively detect only those NOEs involving ligand protons directly attached to ^{13}C or ^{15}N . In a ^{15}N -edited 2D-NOESY experiment on a pepsin/inhibitor (1:1) complex formed with ^{15}N -labelled inhibitors, NOE cross-peaks between the amide protons attached to ^{15}N in the ligand and their neighbouring protons in the protein could be detected. Isotope-editing methods have also been used to study ^{13}C - and ^{15}N -labelled cyclosporin A bound to cyclophilin. It is also possible to use NMR filter experiments to measure ligand–protein NOEs selectively for complexes containing nonlabelled ligand with ^{13}C -labelled proteins; this is a useful approach because it is usually easier to obtain labelled proteins than labelled ligands.

Specificity of Interactions

Information about the groups on the protein and ligand that are involved in specific interactions can be obtained by determining the full three-dimensional structure of the complex in solution. More detailed information about specific interactions can often be deduced by monitoring the ionization states of groups on the ligand and protein and noting any changes accompanying formation of the complex. Further information about specific interactions comes from detecting characteristic low-field shifts for NH protons involved in hydrogen bonds.

Determination of Ionization States

NMR is particularly effective for studying electrostatic interactions involving charged residues on the protein or ligand. A change in the charge state of an ionizable group is usually accompanied by characteristic changes in the electronic shielding of nuclei close to the ionizable group. Thus, NMR can monitor the ionization states of specific groups, measure their pK values and detect any changes that accompany protein–ligand complex formation.

The pK values of histidines in proteins are typically in the range 5.5 to 8.5 and they can easily be studied by carrying out pH titrations of the ^1H chemical shifts of the imidazole ε_1 protons over a suitable pH range and by fitting the data to the Henderson–Hasselbach equation. Ligand-induced changes in the pK behaviour of His residues have been used to monitor interactions in protein complexes formed with novel inhibitors. Protonation states of carboxylate groups in aspartic and glutamic acid residues in proteins have also been studied using ^{13}C NMR on suitably labelled proteins.

When the ionization state is a protonated species, it is sometimes possible to directly observe the proton involved in the protonation using NMR. If the protonation is at a nitrogen atom, then observation of the selectively

Figure 1 Dynamic processes in the complex of trimethoprim with *Lactobacillus casei* dihydrofolate reductase measured at 298 K. Reproduced with permission from Searle MS *et al.* (1988) *Proceedings of the National Academy of Sciences of the USA* 85: 3787–3791.

labelled ^{15}NH group provides an unambiguous method of assigning the bonded proton. Such ^{15}NH proton signals have a doublet splitting (~ 90 Hz) characteristic of one bond ^{15}N – ^1H spin coupling and they can be detected either directly in 1D experiments or by using 2D-HMQC (or HSQC)-based experiments. In a ^1H NMR study examining ^{15}N -enriched trimethoprim in its complex with dihydrofolate reductase (DHFR), a 90 Hz doublet at 14.79 ppm in the spectrum could be assigned to the N-1 proton of bound trimethoprim (see structure in Figure 1). The ^{15}N chemical shift of the N-1 nitrogen is also characteristic of the protonated species (80 ppm different from the nonprotonated species). Earlier studies using $[2-^{13}\text{C}]$ trimethoprim had already shown that the N-1 position is protonated in the bound state and that the pK value for this protonation is displaced by at least 2 units as a result of formation of the complex in which the protonated N-1 group interacts with the γ -carboxylate group of the conserved Asp-26 residue.

Ionization states of phosphate groups can be monitored using ^{31}P NMR and this approach has been used in studies of a coenzyme (nicotinamide–adenine dinucleotide, NADPH or NADP^+) binding to dihydrofolate reductase. In each case the monophosphate group binds in the dianionic form with its pK value perturbed by at least 3 units compared to that of the free ligand.

Hydrogen-Bonding Interactions Involving Arginine Residues

NMR has proved to be a very effective method for studying hydrogen bonding and electrostatic interactions involving side-chains of arginine residues in protein–ligand complexes. These studies are based on detection

of ^1H and ^{15}N NMR signals from NH groups in ^{15}N -labelled proteins using gradient-enhanced two-dimensional $^1\text{H}/^{15}\text{N}$ HSQC NMR experiments where signals for the guanidino NH^ϵ and NH^η nuclei in arginine residues involved in protein ligand interactions can be detected. Such methods have been used on complexes of SH₂ domains formed with phosphopeptides to detect interactions between arginine NH^η hydrogens and phosphorylated tyrosines in the protein. Similar interactions have been studied in complexes of *Lactobacillus casei* dihydrofolate reductase formed with antifolate drugs such as methotrexate where four separate NH^η signals were observed for the Arg-57 residue, indicating hindered rotation in its guanidino group. Two of

the NH^η signals had very low-field chemical shifts characteristic of NH hydrogen-bonded protons. From a consideration of the ^1H and ^{15}N chemical shifts it was possible to deduce that the central pair of NH^η protons in the guanidino group of Arg-57 interact with the α -carboxylate group of the glutamic acid moiety of methotrexate in an end-on symmetrical fashion (see Figure 2). The rates of rotation about the $\text{N}^\epsilon\text{--C}^\zeta$ and $\text{C}^\zeta\text{--N}^\eta$ bonds were determined in the binary and ternary complexes of *L. casei* DHFR with methotrexate and NADPH, and their relative values compared with those in free arginine indicate correlated rotation about the $\text{N}^\epsilon\text{--C}^\zeta$ bond of the Arg-57 guanidino group and the $\text{C}'\text{--C}^\alpha$ bond of the glutamate α -carboxylate group of methotrexate (Figure 2).

Figure 2 (a) Symmetrical end-on interaction of a carboxylate group with the guanidino group of an arginine residue. (b) Structure of methotrexate showing interactions of its α -carboxylate group of the glutamic acid moiety interacting in a symmetrical end-on manner with the guanidino group of Arg-57 of *Lactobacillus casei* dihydrofolate reductase and indicating the correlated rotation about the $\text{N}^\epsilon\text{--C}^\zeta$ bond of the Arg-57 guanidino group and the $\text{C}'\text{--C}^\alpha$ bond of the glutamate α -carboxylate group of methotrexate, which allows the guanidino group to rotate without breaking its hydrogen bonds to the ligand. Mapping Binding Sites by Ligand-Induced Chemical Shifts

A simple method of mapping the interaction sites in a protein–ligand complex involves measuring the ligand-induced chemical shifts accompanying complex formation using the ^1H and ^{15}N chemical shifts of backbone amide NH groups measured in $^1\text{H}/^{15}\text{N}$ HSQC spectra. This method indicates those residues that undergo a change in environment or conformation on complex formation and it works well, even for the case where the full assignments are available only for the uncomplexed protein. In such cases, lower limits for the shift changes can be estimated and these have proved to be adequate for mapping the binding sites. This method can be used for large protein–protein or protein–DNA complexes (up to 65 kDa).

Using these mapping procedures, a very elegant strategy for designing *de novo* ligands with high-affinity binding for selected target proteins has been developed (the so-called SAR (structure–activity relationships) by NMR approach). Large numbers of ligands were screened for their potential binding to target proteins by measuring $^1\text{H}/^{15}\text{N}$ HSQC spectra of the target ^{15}N -labelled protein in the presence of batches of ligands. These spectra could be collected relatively quickly and it was possible to screen up to 1000 compounds per day. This method identifies any ligands perturbing the $^1\text{H}/^{15}\text{N}$ chemical shifts (the binding, if any, usually results in conditions of fast exchange). Once a useful binding ligand has been identified, the protein is saturated with this ligand and the screening is continued to find another ligand that binds noncompetitively with the first one. When a suitable second candidate is found, detailed NMR structural work on the ternary complex is undertaken and, based on the structural information obtained, a strategy is developed for chemically linking the ligands to produce a high-affinity binding ligand. This approach has been used successfully to construct

inhibitors with high binding affinity for metalloproteinases such as stromelysin.

Detection of Multiple Conformations

NMR spectroscopy has proved to be very useful for detecting the presence of different coexisting conformational states in protein–ligand complexes in solution. In some cases the different conformations are in slow exchange such that separate NMR spectra are observed for the different conformations. It is important to characterize the different conformations since each conformation offers a potentially new starting point for the design of improved inhibitors. Recognizing the presence of such conformational mixtures is also important when one is considering structure–activity relationships. NMR is the only method that can provide detailed quantitative information about such conformational equilibria in solution.

Several examples of multiple conformations have been uncovered in NMR studies of complexes of *L. casei* dihydrofolate reductase (DHFR). In many cases the different conformations correspond to a flexible ligand occupying essentially the same binding site but in different conformational states. For example, three conformational states have been detected in the NMR spectra of complexes of the substrate folate with DHFR. Two of the forms have the same pteridine ring orientation as bound methotrexate and their enolic forms can thus bind in a very similar way to the pteridine ring in methotrexate. The other form has its folate pteridine ring turned over by 180°.

Multiple conformations have been detected in several other complexes of *L. casei* DHFR (for example, with NADP⁺ and trimethoprim, and with substituted pyrimethamines) and also in complexes with *S. faecium* DHFR and *E. coli* DHFR: it seems likely that many other protein–ligand complexes will exist as mixtures of conformations. Of course, such conformations are more difficult to detect directly if they are in fast exchange.

Dynamic Processes in Protein–Ligand Complexes

NMR measurements can be used to characterize many of the dynamic processes occurring within a complex: this dynamic information complements the static structural information and provides a more complete description of the complex. Studies using NMR relaxation, line-shape analysis and transfer of magnetization have provided a wide range of dynamic information relating to protein–ligand complexes. The NMR-accessible motions range from fast ($>10^9 \text{ s}^{-1}$) small-amplitude oscillations of fragments of the complex to slow motions ($1\text{--}10^3 \text{ s}^{-1}$)

involved in the rates of dissociation of the complexes, rates of breaking and reforming of protein–ligand interactions and rates of flipping of aromatic rings in the bound ligands; several illustrative examples, mainly from studies of dihydrofolate reductase complexes, are considered below.

Rapid Motions in Protein–Ligand Complexes

Rapid segmental molecular motions ($>10^9 \text{ s}^{-1}$) can be determined by measuring ^{13}C relaxation times and useful information about the binding can be obtained from the changes induced in the motions by the formation of the complex. Protein backbone dynamics are also frequently probed by making ^{15}N T_1 , T_2 , and $\{^1\text{H}\}^{15}\text{N}$ heteronuclear NOE measurements on ^{15}N -labelled proteins and analysing the data using the ‘model-free’ approach suggested by Lipari and Szabo.

Dissociation Rate Constants from Transfer of Saturation Studies

If protons are present in two magnetically distinct environments, for example one corresponding to the ligand free in solution and the other to the ligand bound to the protein, then under conditions of slow exchange separate signals are seen for the protons in the two forms. When the resonance of the bound proton is selectively irradiated (saturated), its saturation will be transferred to the signal of the free proton via the exchange process and the intensity of the free proton signal will decrease. The rate of decrease of the magnetization in the free state as a function of the irradiation time of the bound proton can be analysed to provide the dissociation rate constant. This method has been used to measure the dissociation rate constant for the complexes of NADP⁺, DHFR (20 s^{-1} at 284 K) and trimethoprim. DHFR (6 s^{-1} at 298 K). 2D-NOESY/EXCHANGE type experiments can also be used for such measurements.

Rates of Ring Flipping

Slow and fast rates of aromatic ring flipping have been characterized in ligands bound to proteins. Such studies are facilitated by using ^{13}C -labelled ligands. For example, ^{13}C line-shape analysis on the signals from the enriched carbons in [*m*-methoxy- ^{13}C]trimethoprim and brodimoprim bound to DHFR has been used to measure the rates of flipping of the benzyl ring in the bound ligand. In all cases these rates are greater than the dissociation rates of the complexes and the flipping takes place many times during the lifetime of the intact complex. Thus the measured rate of flipping is indirectly monitoring transient fluctuations in the conformation of the enzyme structure that are required to allow the flipping to proceed.

Hydrogen Exchange Rates with Solvent

Extensive NMR measurements of exchange rates between solvent and labile protons on protein or ligand have been reported. These are usually based on line-shape analysis or transfer of magnetization methods.

Such measurements have been made for the N-1 proton of bound trimethoprim in complexes of ^{15}N -labelled trimethoprim with DHFR. The line shape of the N-1 proton signal varies with temperature owing to changes in the exchange rate of this proton with the H_2O solvent. This line-width data can be analysed to estimate the exchange rate. This exchange can be considered as a two-step process: in the first step the structure opens to allow access of the solvent, and in the second step the exchange process takes place. In this case, the N-1 proton forms and breaks a hydrogen bond with the carboxylate group of the conserved Asp-26 and the measured exchange rate (34 s^{-1} at 298 K) is thus the rate of breaking and reforming this hydrogen bonding interaction. This provides a further example of a very important interaction in the complex breaking and reforming at a rate much faster than the dissociation rate. Thus, individual protein interactions involving both the pyrimidine ring and the benzyl ring are involved in transient fluctuations during the lifetime of the complex (see **Figure 1**). If these structural fluctuations take place in close succession, they could form part of a sequence of events leading to complete dissociation of the complex.

Future Perspectives

It is clear that advances in NMR methodology, particularly in multidimensional NMR experiments used in conjunction with isotopically labelled molecules, will provide even more detailed information about protein-ligand complexes in solution. Improved methods of structure determination will eventually allow the detection of smaller differences in structure between different complexes. The approaches for obtaining structural information from dipolar coupling contributions in the spectra resulting from orienting the molecules in solution (either by using high magnetic fields or by using liquid crystal solvents) has already had an important impact on structural studies of large protein-ligand complexes. There will be increased input into structure-activity relationship (SAR) studies by use of the 'SAR by NMR' method for designing tightly binding ligands as inhibitors of important target proteins, particularly in industrial pharmaceutical laboratories where suitable libraries of compounds are readily available for screening. An improved understanding of the

implications of the dynamic processes taking place within ligand-protein complexes will also emerge. Solid-state NMR studies on ligand complexes of membrane-bound proteins are being undertaken more frequently as the methodology and instrumentation become more widely available: although these studies require demanding isotopic labelling of the ligands, they can provide excellent information about distances and bond orientations that can be used to answer specific questions about the structures of protein-ligand complexes within lipid bilayers. The difficulty of obtaining such information by any other method provides a strong driving force for improving the solid-state NMR approach.

Symbols

A_1, B_0, C_0	MCD parameters (A , B and C terms) defining the amount of absorptive (B_0 and C_0) or derivative (A_1) signals in the MCD spectrum
A	absorbance (unitless)
b	cuvette pathlength (cm)
c	molar concentration (mol L^{-1} ; M)
c	speed of light
$f(E)$	general Gaussian line shape function
g	EPR g values
h	Planck's constant
H_0	external magnetic field
n	refractive index
N	Avogadro's number
T	absolute temperature
α	proportionality constant between the electric field of the light and the electric field at the absorbing centre
β	Bohr magneton
γ	spectroscopic constant
$\Delta A_{\pm}, A_{-}, A_{+}$	change in absorbance, negative absorbance, and positive absorbance, respectively
$\Delta \epsilon_M$	MCD 'extinction coefficient'
ϵ	molar extinction coefficient ($\text{M}^{-1} \text{cm}^{-1}$); ϵ_l and ϵ_r are the specific extinction coefficients for left- and right-circularly polarized light (LCPL and RCPL, respectively)
κ	Boltzmann constant
λ	specific wavelength
ν_0	the position, in nm, of the electronic absorption maximum for a given transition

Introduction and Overview

Magnetic circular dichroism (MCD) spectroscopy is a type of electronic spectroscopy, also called the Faraday effect or the Zeeman effect, that can be a particularly useful and effective method for structural analysis. For example, MCD can be used to assign the transitions in the electronic absorption spectrum (UV-visible), with

respect to details such as the molecular orbital origins of the transitions. Often, such transitions are not clearly observed in the UV-visible spectra, because they are spin-forbidden and weak, but upon application of magnetic field, H_0 , they can be detected. MCD spectroscopy can also be used to determine not only the spin state for a metal such as iron, but also the coordination number at the metal.

There is an extensive body of detailed MCD structural data provided for a variety of different biological, organic, and inorganic systems. However, MCD has been surprisingly neglected, given its broad utility, ease of handling, and low sample-concentration requirements relative to many other spectroscopic methods. MCD spectroscopy has more recently begun to be utilized to its full potential.

Biological systems that have been studied by MCD include: (a) haem (iron porphyrin-containing) proteins and enzymes such as oxygen transport proteins (haemoglobin and myoglobin), electron-transfer proteins (cytochromes), the diverse and ubiquitous P450 enzymes, and peroxide-metabolizing enzymes such as peroxidases and catalases; (b) other biological chromophores such as vitamins B_{12} and chlorophylls; (c) tryptophan-containing proteins (this amino acid has a unique and distinguishing MCD signal); (d) non-haem iron proteins; (e) copper- and cobalt-containing proteins (natural or metal-substituted); and (f) a variety of other systems, too diverse to list here.

One particular advantage of MCD spectroscopy is the limited sample requirements, particularly relative to other experimental methods, even in these days of cloning and massive expression of samples. For example, as much as 500 μL of a 1–2 mM solution of haem protein might be necessary for NMR structural analysis. In contrast, to study the same sample by conventional (electromagnet) MCD, only 2.6 mL of an $\sim 10\text{--}25 \mu\text{M}$ sample is required. Second, the ability to determine key structural information such as spin and coordination states at, or near, biological temperatures is also significant. Whereas the electronic absorption spectrum of a ferric haem protein can generally be used to distinguish high-spin from low-spin systems, more specific information concerning the coordination number was once routinely determined by EPR (also called ESR) spectroscopy. This method not only requires at least 250 μL of an $\sim 250 \mu\text{M}$ sample, it also requires either liquid

nitrogen or liquid helium cooling of the sample to gain the EPR g values and make the assignments. In contrast, MCD spectroscopy of a sample under biologically relevant conditions can provide highly detailed and specific data with respect to both the spin and the coordination states of the system (e.g. high-spin pentacoordinate haem vs high-spin hexacoordinate haem). This has recently been illustrated in the case of the haem catalases, which are among the most rapid of all enzymes, converting H_2O_2 to O_2 and H_2O with a turnover rate of $\sim 100\,000$ per second per active centre (most catalases have four active centres). A novel set of X-ray crystallographic data for bacterial catalase were published, which were not only in conflict with previous X-ray data for a mammalian catalase, but also appeared inconsistent with the rapidity of normal enzymatic activity. Specifically, the ferric haem of the catalase was suggested to have a water molecule as its sixth ligand that was furthermore stabilized by participation in a hydrogen-bonding network. MCD spectral analysis of the identical bacterial catalase, as well as a mammalian, and a fungal catalase, clearly and unequivocally demonstrated that, under approximately biological conditions, all of the native catalases were always high-spin and pentacoordinate, with NO and water ligated at the haem regardless of pH in the range 4–10. Again, this empty coordination site for the haem is of critical significance for the enzymatic reaction of the catalases, where the first step of the reaction requires H_2O_2 ligation at the haem.

In part, the increasing employment of MCD spectroscopy in structural analysis derives from a widening array of modifications that extend the diversity and accuracy of the method. A simple listing of such variations includes:

- (1) method of field generation: electromagnet vs superconducting magnet;
- (2) spectral region studied: near-infrared (near-IR; NIR) vs UV-visible (ultraviolet and visible);
- (3) VT (variable temperature) and VTVH (variable temperature, variable field; $[H_0]$) MCD, using a superconducting magnet, with temperature variations to as low as ~ 1.5 K, and magnetic field variations from ~ 1 to 50 T (1 T = 10 000 G);
- (4) 'fast' MCD, which includes nanosecond and picosecond experiments, using an 'ellipsometric approach', also called TRMCD (time-resolved MCD);
- (5) VMCD, vibrational MCD, particularly Raman;
- (6) the newest modification, XMCD, X-ray detected magnetic circular dichroism.

Fundamentally, MCD spectroscopy can be defined as the differential absorption of left and right circularly polarized light, induced by an external magnetic field (H_0) that is parallel (or anti-parallel) to the direction of light propagation. This property is known as the 'Faraday

Figure 1 Optical components of a typical MCD/CD instrument. The modulator, now most commonly a piezoelectrically driven photoelastic device, converts linearly polarized light to a.c. modulated circularly polarized light.

effect', after Michael Faraday who observed (ca. 1845) that *any* substance, when placed in a magnetic field, will rotate the plane of polarized light. Indeed, it was the Faraday effect that was used to establish the electromagnetic nature of light. A general schematic of an MCD instrument is presented in **Figure 1**.

In the case of *degenerate* electronic transitions, for which the components are not resolved in the absorption spectrum, one has access to only limited structural information. However, in the presence of a magnetic field, these degeneracies are lifted (Zeeman effect) and now can be explored in more detail. Using ordinary (conventional) electronic absorption spectroscopy, no detectable spectral difference is observed for such a sample in the presence or absence of the applied external magnetic field. This is because the spectral line width (for most samples) is greater than the splitting of the energy levels. However, using circularly polarized light it is possible to measure and record the differences between these magnetically degenerate states (see *A* and *C* terms below). For a sample that has no nondegenerate energy levels, it is still possible to obtain an MCD spectrum if the nondegenerate energy levels undergo a magnetically induced mixing; this is the origin of MCD *B* terms. A more detailed analysis is presented below.

MCD vs CD Spectroscopy

Three aspects of MCD spectroscopy are clearly distinct from those of 'natural' circular dichroism (CD) spectroscopy:

- (a) CD requires an optically active, chiral, molecule (essentially one of low molecular symmetry at the chiral centre lacking even a simple mirror plane), whereas MCD has no structural requirements, but rather is a property of *all* matter;
- (b) chirality and optical activity (CD) are derived from the presence of *both* electric *and* magnetic dipole transition moments in the sample under study, which furthermore must be parallel (or anti-parallel) to one another, whereas for magnetic optical activity (MCD) only an electric dipole transition moment is

Figure 2 Cartoon illustrating the photon-induced transitions in a molecule. (a) Electronic absorption from ground to excited state is expressed as shown, where μ_e is the electric dipole moment operator; (b) magnetic absorption and the mathematical expression, where μ_m is the magnetic dipole moment operator; and (c) interaction of electronic and magnetic absorption, yielding optical activity.

required, with the external magnetic field supplying the magnetic component (see **Figure 2**);

- (c) CD spectra are sensitive to molecular structure and perturbations of the chiral centre(s) by the physical environment, which is most clearly seen as asymmetry in the chromophore and/or its environment. MCD spectra are representative of the electronic structural properties of a given molecule, such as field-induced perturbations in energy levels. The latter, however, does *not* imply the absence of environmental sensitivity, but rather that molecular perturbations must directly affect the electronic properties. For example, this may include not only a concentration dependence, but also a sensitivity to structural variations, and to precise ligand geometry surrounding the chromophore (often a metal). MCD reflects electronic structural features such as spin and orbital degeneracies – information about spatial and coordination structure.

Note that in the simplest quantum mechanical expression, for a CD spectrum to be observed there must be both electric and magnetic dipole transition moments, for which the cosine between the two transition dipole moments must be non-zero (**Figure 2**). Essentially, this means that the transition dipole moments must have a parallel (or anti-parallel) relationship to one another. Without all three components (the electric dipole transition moment, the magnetic dipole transition moment, and their parallel relationship) there can be no optical activity.

Extensive theoretical discussions of CD spectroscopy focus on the specific origin of CD activity, such as the ‘one electron model’. MCD differs specifically here from CD, in that MCD spectroscopy provides the external magnetic field, H_0 , whereas chiral systems have their own magnetic transition dipole as a consequence of their very low symmetry at the chiral centre.

MCD Experimental Details

Fundamentally, then, both magnetic circular dichroism and circular dichroism are phenomena dependent upon

the Beer–Lambert law (eqn [1]) that is to say, upon the *concentration* of the sample, and upon the inherent ‘responsiveness’ of the sample under study to light, called the extinction coefficient:

$$A_\lambda = \varepsilon_\lambda cb \quad [1]$$

where A = absorbance (unitless), λ = the specific wavelength, ε = the molar extinction coefficient ($\text{M}^{-1} \text{cm}^{-1}$); c = molar concentration (mol L^{-1} ; M), and b = cuvette pathlength (cm). More specifically, this is written as shown in eqns [2] and [3] for circular dichroism and magnetic circular dichroism, respectively, where ε_l and ε_r are the specific extinction coefficients for left- and right-circularly polarized light (LCPL and RCPL, respectively):

$$A_l^0 - A_r^0 = \Delta A_{\text{CD}}^0 = \Delta A_\lambda^0 = (\varepsilon_l^0 - \varepsilon_r^0) c b \quad [2a]$$

or

$$\Delta \varepsilon^0 = \varepsilon_l^0 - \varepsilon_r^0 \quad [2b]$$

$$\Delta A_\lambda = A_l - A_r \quad [3a]$$

$$= \Delta A_{\lambda(\text{CD})}^0 + H \Delta A_{\lambda(\text{MCD})} \quad [3b]$$

and $\Delta \varepsilon_m = (\Delta \varepsilon - \Delta \varepsilon^0)/H_0 = (\Delta A_\lambda - \Delta A_\lambda^0)/cbH_0$ where A^0 , $\Delta \varepsilon^0$ etc., with a superscript zero represent those values in the absence of a magnetic field. Thus, the actual MCD experiment requires collection of the MCD spectra for both sample and standard (buffer), and collection of the CD spectra for both sample and standard.

The natural CD signal (sample minus buffer) is subtracted from the signal for the sample MCD minus buffer MCD, to yield the ‘raw’ MCD data. These data are then corrected for field strength (in tesla) and for the molar concentration of the sample under study. Note that the MCD intensity is actually dependent on the strength of the magnetic field, H_0 , which is a key factor in the type of MCD experiment described as [3] above. This final correction means that it is actually the MCD ‘extinction coefficient’, $\Delta \varepsilon_M$, that is being reported, and thus one can directly compare the MCD data between different samples in a meaningful manner.

MCD A, B and C Terms; MCD Data Analysis

In the case of ‘natural’ CD spectra, each CD spectral band is generally Gaussian in shape, and is associated with a single optically active transition. In contrast, a given electronic spectrum for a sample can result in several MCD spectral features, given the several different mechanisms by which the spectra feature may arise.

Under experimental conditions of temperature such that Zeeman energies are $\ll kT$, and where the Zeeman

splitting is small compared with absorption line width, there can be three separate contributions to net ellipticity, imaginatively called A , B and C terms. The magnetically degenerate ground or excited states are split by the application of the external field, H_0 .

The MCD spectral magnitude is directly related to the difference between the LCP (left-circularly polarized) and RCP (right-circularly polarized) light, where the (+) and (−) terms below refer to RCP and LCP, respectively:

$$\text{MCD} \propto (\Delta A_{\pm} \equiv A_{-} - A_{+}) \quad [4]$$

Mathematically, MCD is defined as the difference between two transition moments. It is thus differential, and the observed MCD spectrum can be either positive or negative for a given absorption:

$$\Delta A_{\pm} = \gamma \beta H_0 c b [A_1 (-\delta f / \delta E) + (B_0 + C_0 / \kappa T) f(E)] \quad [5]$$

where $\Delta A_{\pm}$ = change in absorption, γ = a spectroscopic constant ($N\pi^2 \alpha^2 \log e / (250 \text{ bcn})$), N is Avogadro's number, α is the proportionality constant between the electric field of the light and the electric field at the absorbing centre, b is Planck's constant, c is the speed of light, n is the refractive index, β is the Bohr magneton, H_0 is the magnetic field strength, κ is the Boltzmann constant, and T is the absolute temperature. The term $f(E)$ is a general Gaussian line shape function, and thus eqn [5] has contributions from both the line shape and derivative of the line shape. A_1 , B_0 and C_0 are the MCD parameters (A , B and C terms) defining the amount of absorptive (B_0 and C_0) or derivative (A_1) signals in the MCD spectrum.

The A_1 term can *only* be non-zero if *either* the ground or the excited state is degenerate and is Zeeman split by longitudinal magnetic field; the derivative line shape function for A_1 in eqn [5] results in its characteristic shape. An A term is most easily described for degenerate excited states (Figure 3). Because there is a frequency shift between the two transitions, there cannot be cancellation of equal and opposite ellipticity, so the 'derivative shaped' A term is observed. (Note the important distinction that while this feature is shaped like a derivative, it is *not* one in actuality, being a difference spectrum.) Two diagnostic features of an A term are (1) that it is centred at ν_0 , which means that the 'zero-point' where the MCD band goes from negative to positive or vice versa, corresponds exactly (in practice, very closely) with the electronic absorption spectral maximum of the sample, and (2) the intensity of the MCD A terms is invariant with temperature, and thus is independent of temperature.

The C_0 term is analogous to A_1 , in that it is only non-zero if there is a degeneracy; however for C_0 this must be a ground-state degeneracy. The C_0 term is absorptive in nature and also has an associated temperature dependence, which means that the extent of its contribution to the MCD line shape varies with absolute temperature. Assuming thermal equilibrium for the electronic states, the populations are dominated by Boltzmann statistics. Thus as the temperature is lowered, the lower energy level of the degenerate ground state has an increasing population, and the C term increases in intensity. Indeed, the inverse correlation between MCD intensity and absolute temperature is a distinguishing feature of the C term. This is illustrated in Figure 4. Again, in comparison with the A

Figure 3 Origin and typical spectrum of an MCD A term. (a) Electronic transition from ground to degenerate excited state; on the right, in the presence of the magnetic field, H_0 , the excited state degeneracy is split. This results in separate transitions, corresponding to the differential absorption of left or right circularly polarized light. (b) The separate left (ϵ_l) and right (ϵ_r) circularly polarized spectra; ν_0 is the position of the absorption maximum. By convention, the absorption of left circularly polarized light is positive and absorption of right circularly polarized light is negative. (c) The A term MCD spectrum, $\Delta\epsilon = \epsilon_l - \epsilon_r$; note that the position of ν_0 is at the 'crossover' (zero-point) of the derivative-shaped A term. This change of sign for the MCD signal at the position of the absorption maximum is diagnostic for an A term.

Figure 4 Origin and typical spectrum of an MCD 'C' term. (a) Electronic transition from degenerate ground to excited state; on the right, the magnetic field, H_0 , splits the excited state degeneracy. This results in separate transitions, corresponding to the differential absorption of left or right circularly polarized light. (b) The separate left (ϵ_l) and right (ϵ_r) circularly polarized spectra; ν_0 is the position of the absorption maximum. (c) The C term MCD spectrum, $\Delta\epsilon = \epsilon_l - \epsilon_r$; note that the ν_0 absorption maximum is not in any particular relationship to the resulting C term spectrum. The C term intensity is inversely dependent upon temperature, due to Boltzmann population of energy levels; as the temperature decreases, more of the molecules populate the lower of the two degenerate orbitals, and thus the C term intensity increases as the temperature is lowered, until the saturation point.

term, the C term is not derivative shaped, nor does it have a zero-point that corresponds with the absorption spectral maximum of the correlated electronic transition. For both the C term and the B term (discussed below), the positions of the absorption maximum correlates with the MCD band position, as either a maximum (positive MCD band) or a minimum (negative MCD band).

Finally, there is the B term of the MCD spectra, which is a complex species deriving from the mixing of electronic states. The quantum-mechanical origin of the B_0 term is the magnetically induced mixing of non-degenerate states. The wide spacing of energy levels generally results in a small B_0 term. The B_0 term is, like the C term, Gaussian in shape. However, the B term is the temperature-independent portion of the normal absorptive line shape of eqn [5]. To some extent, the MCD spectrum can be considered to be an extension of electronic absorption spectroscopy, revealing a great deal more specific and precise information. This simplification, of course, neglects the information that MCD can provide with respect to magnetic parameters of a transition. As shown in Figures 3 and 4, the MCD spectrum not only has band position and intensity for each transition, but also *sign* hence there is more information 'content' provided.

One additional MCD term should be defined: D_0 , the dipole strength, such that

$$A/E = \gamma D_0 f(E) \quad [6]$$

Mathematically, the magnetic g values for the state involved in the electronic transitions are directly related to the ratios A_1/D_0 and C_0/D_0 . Plotting $\Delta\epsilon$ vs $\beta H/2kT$ (this graph is called an MCD magnetization curve) permits

the determination of the magnetic properties (g values) of the ground and excited states, C_0 and A_1 . Although the g values determined in this manner are not as precise as those obtained by EPR spectroscopy, they have proved useful. Indeed, the use of group theoretical techniques to calculate MCD parameters is a major factor in the use of the MCD for assignment of energy states. A second key factor, discussed above, is the common ability to use sample concentrations that are an order of magnitude weaker than needed for other structural methods.

Experimental Variations on MCD Spectroscopy

The 'basic' MCD instrument is similar to that used for electronic absorption spectroscopy, with the exception that the light must be circularly polarized (see Figure 1). A photoelastic modulator (PEM) inputs linearly polarized light, and converts it into circularly polarized light, with RCP and LCP being generated alternatively. The detector observes a signal fluctuation at the ~ 50 Hz frequency and this a.c. signal is input into a sensitive amplifier, capable of detecting very small intensity differences. The sample itself is placed between the two poles of the magnet, and the magnet itself is oriented so that the direction of the field, H_0 , is parallel (or anti-parallel) to the directions of propagation of the light.

Variations in Method of Field Generation, Electromagnet vs Superconducting Magnet

Some systems use a simple electromagnet, capable of producing magnetic fields up to 1.5 T (15 000 G). This

method is simple and rapid, in that it only requires cooling water and temperature regulation for the sample. In contrast, other MCD systems use superconducting magnets, which have more demanding experimental constraints (such as liquid helium cooling and a longer 'setup' time prior to onset of experimental data collection), but are capable of generating magnetic fields as large as 50 T.

Variations in the Spectral Region Studied

Near-infrared (near-IR, NIR) vs UV-visible (ultraviolet and visible): both electromagnets and superconducting magnets can be used successfully not only in the more common $\sim 800\text{--}200\text{ nm}$ spectral regions (UV-visible), but also in the near-IR region. There has been considerable success in the assignment of the axial ligands to biological haem systems through study of MCD data for the near-IR region.

VT and VTVH MCD

These are variable-temperature MCD and/or variable temperature, variable-field MCD, respectively using a superconducting magnet, with temperature variations to as low as $\sim 1.5\text{ K}$ and magnetic field variations from ~ 1 to 50 T.

VTVH MCD is used to study ground-state electronic structure such as ground-state splittings, especially for non-Kramers ions which do not always have EPR spectra. This approach is a generally useful probe of the ground-state electronic properties of paramagnetic metal ions. MCD is not a 'bulk property technique' like magnetic susceptibility, so is not prone to errors due to paramagnetic impurities. MCD spectroscopy, because it is a type of electronic absorption spectroscopy, can zero in on specific metal ions. VTVH can determine 'single-ion zero field splitting (ZFS)' and the exchange coupling constant, J . In comparison, EPR cannot be used in systems that are non-Kramers, even spin systems with large ZFS. Once the ground-state electronic properties are known, then one can determine changes in J or in ZFS. This approach, with examination of samples at very low temperatures, down to 1.5 K, is still an absorptive method, so the sample must be optically transparent. This is generally accomplished by dissolution of the sample in, e.g. 50:50 glycerol-buffer (aqueous media).

Low-temperature MCD spectroscopy is an extremely useful tool to distinguish between electronic transitions arising from a diamagnetic ($S=0$) ground state and transitions arising from a paramagnetic ($S>0$) ground state. This is because the $S=0$ level is nondegenerate, and thus cannot provide a temperature-dependent C term in the presence of the magnetic field.

'Fast' MCD, Also Called TRMCD (Time-Resolved MCD)

For reviews of the methodology and applications of nano- and picosecond MCD experiments, see the Further reading section. This approach has required extensive modification of the equipment used for sample analysis, in particular using elliptically polarized light. This work has led to exciting results, permitting the examination of transient molecular species. Applications of nanosecond MCD have focused primarily on ligand complexes of haem proteins and their photo-produced dissociation intermediates, particularly given the intense absorption maxima of haem systems (typical ϵ $100\,000\text{ M}^{-1}\text{ cm}^{-1}$), and their strong MCD signals even at room temperature.

To date, the experimental focus has been on systems with unpaired spins (metal complexes), rotational symmetries (aromatic molecules such as the amino acid tryptophan, porphyrins), and metalloporphyrins (haem proteins). An exciting application came from TRMCD of the photodissociated CO adducts of, e.g. haem proteins such as mammalian cytochrome c oxidase: the diamagnetic, low-spin, hexacoordinate Fe(II), of the ferrous-CO haem becomes a paramagnetic high-spin, pentacoordinate Fe(II), with a concomitant appearance of a new C term. In the case of picosecond TRMCD, picosecond lasers are used. One such application demonstrated that upon photodissociation of the CO ligand bound to the haem protein myoglobin, the change from a hexacoordinate to a pentacoordinate haem occurred, 'within the 20 ps rise time of the instrument'.

VMCD, Vibrational MCD, Particularly Raman

Magnetic Raman optical activity determines transitions of electrons among energy levels created by an applied external magnetic field; problems arise here owing to limitations in the field strength. MVCD (magnetic vibrational CD) splits degenerate levels of vibrational transitions and aids in the analysis of bonding.

X-ray Detected Magnetic Circular Dichroism (XMCD)

This technique has recently evolved into an important method for magnetometry. This technique has unique strengths in that it can be used to determine quantitatively spin and orbital magnetic moments for specific elements, and can also be used to determine their anisotropies through analysis of the experimental spectra. For example, XMCD has been applied to the study of thin films of transient metal multilayers, such as Cu or Fe.

The XMCD method is one where the properties of $3d$ electrons are probed by exciting $2p$ core electrons to unfilled $3d$ states. The $p \rightarrow d$ transition dominates the

L-edge X-ray absorption spectrum. L-edge X-ray spectroscopy of iron has proved to be useful because the transitions from the $2p$ ground state to $3d$ excited states are strong and dipole allowed, and the small natural line widths also indicate potentially strong MCD spectra. The intense L-edge XMCD spectra of the iron-sulfur protein rubredoxin and of the 2Fe-2S centre of *Clostridium pasteurianum* have also been studied. Both the XMCD sign, and its field dependence, can be used to characterize the type of coupling between magnetic metal ions and the strength of such coupling.

Conclusion

MCD spectra can profitably separate contributions from multiple metal centres to a protein electronic spectrum, be used to evaluate metallo-biological systems without complications from the protein 'milieu', determine zero-field splitting, assign electronic transitions, provide information about a chromophore's electronic structure, evaluate theoretical models, obtain magnetic properties (g values, spin states, magnetic coupling) and be used for structural comparison of 'model' and biological systems.

Modern MCD spectroscopy can only prove to be increasingly useful. Whereas the standard (electromagnetic) instruments available in the 1970s and 1980s could require up to ~ 45 min per single scan of the data (not counting the buffer, CD, and CD of buffer scans), modern multi-scanning capability permits a significant improvement in signal-to-noise ratio. This has a concomitant advantage in permitting careful and detailed studies to be performed.

Perhaps the greatest utility of MCD spectroscopy is in concert with other methods. No one spectroscopic or structural analysis method can have 'all the answers'. Only a consistent overall structural picture, provided by analysis of data from several methods, with awareness of the shortcomings of each, can lead us closer to the desired 'truth' with respect to the systems under study.

ϕ	magnetization phase

Introduction

In the 1990s pulsed field gradients became a more common element in multiple-pulse high-resolution NMR methods. Gradients have been incorporated into these sequences to improve water suppression, to spoil radiation damping, to remove undesired signals, and to collect faster or higher-resolution multidimensional spectra. Although the potential for pulsed magnetic field gradients has been known since the early years of NMR, only recently has the performance of gradient systems been sufficient to take full advantage of this tool. There are essentially four ways in which gradients are used: coherence pathway selection, spatial encoding, diffusion weighting and spoiling, all used in modern high-resolution systems. These methods have common and differentiating elements. Coherence selection and diffusion weighting take advantage of the reversible behaviour of the pulse gradient effect. Spoiling is a subset of coherence pathway selection that requires no encoding gradient and hence no read or rephase gradient. Spatial encoding can be used to image and correct B_0 inhomogeneity, and can be used to restrict the detected sample volume. The basic elements of B_0 field gradients, as used in high-resolution NMR, are described.

Basic Properties of Gradients

On a typical high-resolution NMR system, a B_0 gradient probe can transiently generate a linear change in the otherwise homogeneous B_0 field of ± 1 mT or moreover the approximately 2 cm z sample length. Many gradient systems can also independently generate linear transverse (x and y) gradient fields of similar magnitudes. Linearity, switching speed and gradient recovery times are important gradient performance criteria. The switching time or recovery time was the most significant limitation of early gradient systems. In these early designs, the gradient field was not constrained inside the gradient cylinder, as shown in **Figure 1a**, and the process of generating a transient gradient interval induced undesirable currents in nearby conductors, especially the components of the magnet itself. These induced eddy currents in turn generate magnetic fields that perturb the NMR spectrum. These stray fields cause significant spectral distortions and last for hundreds of milliseconds. It was therefore impossible to maintain reasonable timing in multiple-pulse NMR experiments using this type of gradient. The invention of the actively shielded gradient coil in the late 1980s removed this limitation by constraining the gradient field inside the gradient cylinder, as illustrated in **Figure 1b**. This innovation and the development of dedicated high-resolution NMR gradient probes have made this technology readily available to NMR spectroscopists.

The Gradient Pulse Effect

A gradient in the B_0 field across a sample will cause the spins in that sample to precess at spatially dependent rates. More specifically, a gradient pulse will add a reversible, spatially dependent, and coherence order-dependent, phase to the magnetization:

$$\phi_r = \gamma p r G t \quad [1]$$

where γ is the magnetogyric ratio, r is the distance from gradient isocentre, G is the gradient amplitude, t is the gradient pulse duration and p is coherence order. If not resolved in space, or rephased, the impact of a spatially dependent phase across the detected volume is self-cancellation of signal. In the absence of B_1 , radiofrequency

Figure 1 (a) Current diagram for conventional unshielded z gradient coil. (b) Current diagram for actively shielded z gradient coil.

magnetic field inhomogeneity and susceptibility shifts, in a detected region $\pm \frac{1}{2} r_{\max}$, the impact of a gradient pulse on pure x magnetization ($p = 1$) will be:

$$M_x(t) = 2\gamma G r_{\max} t \sin\left(\frac{1}{2}\gamma G r_{\max} t\right) \quad [2]$$

Under these idealized conditions, perfect cancellation occurs at multiples of $\phi(r_{\max}) = 2\pi$ but practical dephasing requires many cycles of 2π , where residual signal can be approximated as $2/(\gamma G r_{\max})$. Thus, a typical 1ms 0.25T m^{-1} gradient pulse over a 1.5cm B_1 sample volume would reduce the observable proton signal by a factor of about 1000. For pathway selection, it is the difference in gradient integrals that determine the level of suppression. Of course, practical matters such as gradient linearity (especially the fall-off at the ends of

the sample volume), and B_1 homogeneity, will determine the actual suppression.

Coherence, Coherence Order and Pathway Selection

Coherence is a generalization of the idea of transverse magnetization. Coherence order is the quantum number difference associated with the z component of the rotation generated by the RF excitation, and can only be changed by another RF pulse. Thus, coherence order is conserved in the time periods separating RF pulses, during which the application of a gradient pulse will encode magnetization according to the coherence order of that interval. The route of the observed magnetization is referred to as the coherence transfer pathway. All pathways start at $p = 0$ (thermal equilibrium) and must

end with single-quantum coherence to be detectable. Transverse magnetization is a specific type of coherence characterized by the single-quantum coherence levels $p = +1$ and -1 . Both components are detected to distinguish positive and negative frequencies in a quadrature receiver. By convention, $p = -1$ represents the quadrature detected signal, $s(t) = s_x(t) + i s_y(t)$.

Coherence transfer pathway diagrams are a good way to visualize the need for pathway selection in multiple-pulse NMR experiments. These pathways remind us that each RF pulse transfers magnetization to multiple coherence levels, only one or two of which must be retained to end up with the desired artefact-free spectrum. The traditional way to select a given pathway is to apply phase cycling. With phase cycling, the pulse sequence is repeated, using changes in the phase of the RF pulses, along with addition or subtraction of the corresponding complex signals to retain the desired pathway and cancel all the others. As a difference method, phase cycling can become a problem when the desired pathway is much smaller than the unwanted ones, as is the case in many multiple-quantum experiments. As a nondifference method, pulsed field gradient selection of the pathway is an advantage in these cases.

Coherence transfer pathways are also a convenient way to visualize the action of gradient pulses in an NMR sequence, since the spatial encoding of each interval in the pathway is directly proportional to the product of gradient integral, Gt , and coherence order, p . Any pathway in which the sum

$$\sum_i p_i(Gt)_i = 0 \quad [3]$$

will be passed. Pathways where this is not true will retain a spatially dependent phase and will self-cancel.

The pathway for homonuclear correlation spectroscopy (COSY) is shown in **Figure 2** and provides a simple example. The first pulse creates coherence with orders $+1$ and -1 and leaves some z magnetization as coherence order 0 . Thus, there are three pathways by which the coherence can reach the receiver after the

second RF pulse, namely $[0 \rightarrow 0 \rightarrow -1]$, $[0 \rightarrow +1 \rightarrow -1]$ and $[0 \rightarrow -1 \rightarrow -1]$. If the RF carrier is placed on one side of the F2 spectrum, all of the peaks in the 2D spectrum corresponding to the $[0 \rightarrow -1 \rightarrow -1]$ coherence pathway will lie on one side of $F_1 = 0$ and the peaks from $[0 \rightarrow +1 \rightarrow -1]$ will lie on the other side of $F_1 = 0$. The $[0 \rightarrow 0 \rightarrow -1]$ peaks will occur only at $F_1 = 0$. A single gradient pulse placed between the two RF pulses will spoil coherence that passes through both $p = +1$ and $p = -1$, and will select the $[0 \rightarrow 0 \rightarrow -1]$ pathway. The addition of a read gradient interval after the second RF pulse will allow one of the other two pathways to be selected. If the read gradient is equal in sign and integral to the first (encode) gradient, then the pathway that goes through the $[0 \rightarrow +1 \rightarrow -1]$ transfer will be selected, while the coherence that remains at -1 during evolution and acquisition $[0 \rightarrow -1 \rightarrow -1]$ will be selected by a gradient of equal integral but opposite sign.

Multiple-Quantum Coherence Transfer Selection

A common usage of pulsed field gradients is multiple-quantum coherence transfer selection, which takes advantage of the nondifference filtering of large unwanted signals from the small desired ones. The simplest homonuclear example is the three pulse sequence shown in **Figure 3**. Homonuclear scalar coupled spins will give rise to both double and zero quantum coherences in the mixing time (t_m) interval. Uncoupled spins, such as solvent water, will not and thus the use of a 1:2 ratio of gradients ($G_1:G_2$) will select only coupled spin coherence that goes through the $[0 \rightarrow +1 \rightarrow -1 \rightarrow +2 \rightarrow -1]$ pathways. A spoiler gradient (G_1 only) during the mixing time will select for pathways that go through $p = 0$ in the mixing time, selecting the zero-quantum pathway plus any residual z magnetization. A single pathway $[0 \rightarrow +1 \rightarrow +2 \rightarrow -1]$ is selected using a 1:1:3 gradient sequence. This is achieved by adding a gradient of integral I during t_1 evolution time and increasing the read

Figure 2 Coherence-transfer pathway diagrams for COSY, illustrating gradient selection of (a) the $F_1 = 0$ artefacts only, $[0 \rightarrow 0 \rightarrow -1]$; (b) N-type signals, $[0 \rightarrow +1 \rightarrow -1]$; and (c) P-type signals, $[0 \rightarrow -1 \rightarrow -1]$.

Figure 3 Coherence transfer pathway diagram for homonuclear double-quantum selection with gradients.

gradient at the start of the t_2 interval by the same area. These methods are all very good at suppressing the uncoupled water signal and reducing t_1 -noise. However, both double-quantum and zero-quantum sequences may also pass water or other large solvent signals via the dipolar field effect unless the gradients are oriented at the magic angle 54.7° where triple axis gradients are used ($G_x = G_y = G_z$). Heteronuclear multiple-quantum selections, often for protons attached to a lower magnetogyric ratio nucleus, are also very common applications of gradient selection. In this case it is often convenient to generate a combined coherence transfer pathway diagram for coupling partners and to use normalized heteronuclear coherence order p' , scaled to the proton magnetogyric ratio. The resulting normalized coherence levels are then directly related to the sensitivity to pulsed field gradient integrals. The coherence pathway diagram for the gradient-enhanced heteronuclear multiple quantum correlation (HMQC) experiment is illustrated in **Figure 4**. For $X = {}^{13}\text{C}$, the initial heteronuclear double-quantum level p' [$\text{H}(+1):{}^{13}\text{C}(+1)$] = 1.25, and the initial heteronuclear zero-quantum level p' [$\text{H}(-1):{}^{13}\text{C}(+1)$] = -0.75. In this example, gradient ratios of 4:0:5 or 0:4:-3 or 4:4:2 would all select for the same pathway through the double $\rightarrow$ zero-quantum transfer, and spoil the zero $\rightarrow$ double-quantum transfer pathway, as well as coherence pathways for proton spins not coupled to a ${}^{13}\text{C}$ nuclei.

As in the homonuclear case, this method provides excellent water suppression. The suppression of the t_1 -noise artefacts is so good with these methods that data can be collected under conditions that are not possible with traditional phase cycled methods. This advantage has been exploited especially in long-range proton-carbon correlation studies of polymer branching, as illustrated in **Figure 5**, and for proton-proton correlation at the water chemical shift frequency.

Figure 4 Coherence transfer pathway diagram for gradient-enhanced HMQC sequence. The pathway illustrated by the solid line selects the pathway through heteronuclear double-quantum [$\text{H}(+1):\text{X}(+1)$] and heteronuclear zero-quantum [$\text{H}(-1):\text{X}(+1)$] levels. For $X = {}^{13}\text{C}$, this pathway can be selected by any of the gradient ratios 4:0:5, 0:4:-3 or 4:4:2.

Spin Echoes and Gradient Pulses

Spin-echo selection with gradient pulses was the first and is probably now the most common use of gradients in magnetic resonance. This element is common to MR imaging, localized spectroscopy, diffusion measurements, water suppression and artefact reduction in multiple-pulse NMR. On high-resolution spectrometers, where all of the B_1 sample volume is normally detected, RF refocusing pulses produce a considerable fraction of non- π rotation. The placement of equal gradient pulses on either side of the π pulse, as illustrated in **Figure 6a**, filters out any coherence that does not refocus ($p \rightarrow -p$ transition). This is also an especially effective method for improving the performance of frequency-selective π pulses such as are used in the gradient-enhanced version of spin echo water suppression (SEWS). Gradients of equal integral, but opposite sign, placed on either side of a chemical shift selective refocusing pulse, such as the 1-1 binomial example shown in **Figure 6b**, are a powerful way to capture a selective, refocused ($p \rightarrow -p$ transition) bandwidth. This approach can be used to dramatically avoid residual out-of-band signal (e.g. water) relative to the phase-cycled method. Frequency-selective suppression using spin echoes and gradients has also proved very successful in methods such as WATERGATE (water suppression by gradient tailored excitation) and MEGA as illustrated in **Figures 6c** and **6d**. In addition to $p \rightarrow -p$ transfer, π pulses invert z magnetization, $I_z \rightarrow -I_z$. In this case imperfect π pulses will generate transverse magnetization. To select for the $I_z \rightarrow -I_z$ transition and spoil both transverse magnetization and the $p \rightarrow -p$ refocused magnetization, nonequal gradients can be applied before and after a p

Figure 5 Gradient (b and d) versus phase-cycled (a and c) HMBC spectra of the polymer PI-b-PS. The comparative traces at $F_2 = 1.7\text{ ppm}$ show the far superior signal-to- t_1 -noise achieved by the gradient method (d) relative to the traditional phase-cycled approach (c). Reproduced with permission of The Society of Chemical Industry and John Wiley & Sons, from Rinaldi P, Ray DG, Litman V, and Keifer P (1995) The utility of pulse-field gradient-HMBC indirect detection NMR experiments for polymer structure determination. *Polymer International* 36: 177–185.

inversion pulse (Figure 6e). Each gradient pulse will spoil any transverse magnetization during those intervals, and the nonequal integrals of the gradients will prevent the refocusing of the $p \rightarrow -p$ transition. The selection of $I_z \rightarrow -I_z$ transitions are also useful in multinuclear experiments, in which case the gradient dephasing of S coherences must be avoided. This can be accomplished by using gradients of equal integrals but opposite sign (Figure 6f). The second gradient will reverse any accumulated phase for the S spin caused by the first gradient, but will still spoil all I spin coherences except of the $I_z \rightarrow -I_z$ transitions.

Spoiling

A gradient spoiler pulse can be applied in intervals where the desired signal has coherence order $p = 0$. These applications include gradient-enhanced z and zz filters, stimulated echo selection, multiple-quantum suppression during NOESY (nuclear Overhauser effect spectroscopy) mixing times and the homonuclear zero-quantum methods as previously described. Two examples of this gradient element are illustrated in Figure 7.

The gradient-enhanced z filter is a pulse field gradient version of the multiple-acquisition nongradient method.

Figure 6 The use of gradients with RF π pulses. (a) Standard spin echo selection, $p \rightarrow -p$ transitions are selected. Any imperfection in the RF refocusing is cancelled. (b) Frequency-selective spin echo selection. Only the spins in the refocused bandwidth are selected. (c) Pathway for MEGA. Spins that are refocused by the selective RF refocusing pulse are dephased by the G_1 : G_2 gradient pair. Outside the frequency-selective bandwidth, G_2 reverses the effect of G_1 . (d) Pathway for WATERGATE. A net zero RF rotation leaves signals in the frequency-selective bandwidth dephased by the G_1 : G_2 pair, while spins outside the selective bandwidth are rephased as in (a). (e) Selection of I_z to $-I_z$ ($p = 0 \rightarrow 0$) transitions uses nonequal gradients prior to the π pulse to eliminate any existing transverse magnetization, and after the π pulse to eliminate any transverse magnetization generated by RF pulse inhomogeneity. (f) Selection of I_z to $-I_z$ ($p = 0 \rightarrow 0$) in a heteronuclear sequence while preserving any nonzero S coherence levels.

In the original method, magnetization is stored as I_z , and multiple delay times are collected to allow non- I_z magnetization to evolve and self-cancel. The gradient method accomplishes this in a single step. As shown in **Figure 7a**, the two-pulse RF filter acts as a π pulse for the desired magnetization, which means the spoiler during the I_z interval can be combined with a spin-echo gradient pulse pair outside the I_z interval.

The gradient-enhanced zz filter selects for heteronuclear longitudinal spin order described by the density operator $I_z S_{zz}$, and can be easily integrated into the

heteronuclear single quantum correlation (HSQC) type sequences, or as a preparation period for HMQC methods. The gradient version of the zz filter as shown in **Figure 7b** also passes I_z magnetization and is not as efficient at rejecting unwanted pathways as coherence selection.

Spoiler gradients can also be used following frequency-selective excitation to eliminate a narrow band of chemical shift. This approach is often referred to as a chemical shift selective (CHESS) pulse. Optimum performance requires the tip angle of the selective excitation pulse be adjusted for water T_1 relaxation that occurs during the excitation–dephase intervals. Multiple excitation–dephase intervals can be concatenated to achieve a moderate level of B_1 and T_1 insensitivity. Alternatively, T_1 -recovery time and water excitation flip angle can be adjusted to exploit differences in the solute and the water T_1 values and to allow significant recovery of the solute spins during the time it takes water to reach a null. Like many gradient methods, the T_1 -delayed CHESS pulse inherently eliminates the radiation damping effect and makes it possible to take advantage of the true water T_1 .

Diffusion-Weighted Water Suppression

In any experiment where gradients are used to label spins with a spatially dependent phase, which are subsequently rephased with a second gradient pulse, there will be a loss of signal due to any movement of the spins during the time interval between labelling and rephasing. For a spin-echo ($p + 1 \rightarrow -1$) transition, this loss of signal is related to translational diffusion by the Stejskal–Tanner equation:

$$\ln(S/S_0) = -\gamma^2 g^2 \tau^2 (\Delta) - \left(\frac{1}{3} \tau\right) D \quad [4]$$

where γ is the magnetogyric ratio, g is the strength, and τ the duration of the gradient pulse pair, Δ is the time between gradient pulses, and D is the diffusion coefficient. Normally, diffusion weighting is minimized by using modest gradient integrals (g and τ) and by keeping the separation (Δ) between the encode and rephase portion of a gradient pair small. However, by increasing both gradient integrals and separation (Δ), it is possible to take advantage of the significant differences in the translational diffusion of solvent water and large solute molecules such as proteins. This is the basis of the DRYCLEAN, diffusion reduced water signals in spectroscopy of molecules moving slower than water. With a modest 20-fold difference in diffusion constant, D , a gradient pair could be selected to preserve over 70% of the solute signal, while suppressing water by 1000-fold. It is important to note that, like multiple-quantum coherence pathway selection, this method is also

Figure 7 (a) Gradient-enhanced z filter and (b) zz filter. As in the inversion examples shown in **Figure 6**, these gradients dephase all but $p = 0$ coherence order.

independent of the width and shape of the water signal. The same basic gradient-selected spin-echo methodology is also used to study exchange processes in biomolecules.

Phase-Sensitive Methods

Modern multidimensional spectra are almost always recorded in pure absorption mode. The primary reasons are phase sensitivity, improved resolution, and a $\sqrt{2}$ factor increase in SNR compared with magnitude mode. Pure absorption phase is obtained from the amplitude-modulated signal in t_1 , separating the frequencies of the two mirror image pathways, $p = +1$ and $p = -1$ in an evolution time analogue to quadrature detection. In methods without gradients, or in methods that use gradients only for spoiling, spin echo and/or I_z inversion selection, this is accomplished using a two-step phase cycle for each t_1 increment. Both steps contain $p = +1$ and $p = -1$ coherence, and the combination provides frequency discrimination at full signal intensity. Pure absorption line shape with gradient selection during evolution is also a two-step process, but each acquisition contains only $p = +1$ or $p = -1$, leading to a $\sqrt{2}$ factor loss in SNR relative to the phase-cycled selection of quadrature in F_1 . The trade-off is that signal-to- t_1 noise is often better for the gradient methods, as illustrated in **Figure 5**, and in the instances where pure absorption line shape is not required the gradient selection methods are significantly faster. Unlike the single-step selection with gradients, phase-cycled methods require multiple steps to separate $p = +1$ or -1 . The advantage of a reduction in required phase cycle steps is most evident in three- and four-dimensional NMR studies, where proper sampling of the evolution time alone

generates more signal averaging than necessary. It is possible to collect separate $p = +1$ and $p = -1$ pathways in a single acquisition per t_1 time by using the switched acquisition time (SWAT) gradient method. In this method the two coherence pathways are alternately and individually acquired on alternate sampling points in the digitizer. Although a doubling in F_1 bandwidth still results in the $\sqrt{2}$ factor loss in SNR, this approach offers the ability to collect pure absorption multidimensional data in a minimum total acquisition time. The method, however, is very demanding on gradient switching time.

Spatial Selection

In the typical high-resolution NMR experiment, the entire B_1 volume contributes to the final result. The volume of spins in the transition band where the relatively linear B_1 field falls from maximum to zero can be significant. This inhomogeneity and line shape distortions from bulk susceptibility effects also found at the ends of the sample are among the reasons why gradient selection and phase cycling methods are so heavily used for artefact reduction in multiple-pulse NMR. A gradient-based method that can be used to reduce these end effects (transition band suppression or TBS) uses slice select-spoil intervals during the pulse sequence preparation period to avoid this difficult region of the sample. Combination of TBS with T_1 -delayed CHES pulses and gradient selection of double-quantum coherence makes it possible to study proton-proton correlations at the water chemical shift in both F_1 and F_2 . The pulse sequence and an example are shown in **Figure 8**.

Another application of spatial localization in high-resolution NMR applies to the specialized field

Figure 8 (a) Pulse sequence for phase-sensitive version of gradient-enhanced double-quantum correlation method incorporating T_1 delayed CHES sequence and TBS. (b) Phase-sensitive contour plot of data for 1mM ubiquitin in 90% H_2O –10% D_2O collected using this method. A water inversion null time of 200 ms was used to allow $C\alpha H$ protons at 4.8 ppm to recover fully as expansion near $F_2 = 4.8$ (water) illustrates. Reproduced from Hurd R, John B, Webb P and Plant P (1992) *Journal of Magnetic Resonance* 99: 632–637 with permission of Academic Press.

of high-performance liquid chromatography–NMR (HPLC–NMR). With NMR as the detector for a liquid chromatography system, it can be valuable to spatially resolve the NMR sample volume. This can be done by phase encoding, which allows the data to be retrospectively processed to eliminate end effects or to separate partially overlapping HPLC fractions.

Field Maps and Homogeneity Adjustment

One relatively obvious application of three-axis gradients is to image and correct for any B_0 field inhomogeneity. Three-dimensional phase or frequency maps can be obtained and used to image the inhomogeneity of the sample, and with previously obtained maps for fixed offsets of the known shims a best-field solution can rapidly be made. Normally this approach works best with a strong solvent signal such as water, but in a limited way it can be accomplished using the deuterium-lock solvent signal.

Summary

Gradients are useful as an integral part of multiple-pulse NMR methods. High-resolution NMR systems and probes continue to incorporate these devices and accordingly the use of these tools continues to become more common. In many ways, gradients are a perfect partner for the limitations of the native high-resolution NMR B_1 fields, and also work complement only to crafted RF pulse methods. When used appropriately, gradients have the ability to enhance the quality of most multiple-pulse NMR results.

Principle of MFM

In magnetic force microscopy (MFM), the magnetic stray field above a very flat specimen, or sample, is detected by placing a small magnetic element, the tip, mounted on a cantilever spring very close to the surface of the sample (Figure 1). Typical dimensions are a cantilever length of 200 μm , tip length of 4 μm , and diameter of 50 nm and a distance of 30 nm from the surface. The force on the magnetic tip is detected by measuring the displacement of the end of the cantilever, usually by optical means. The forces measured in typical MFM applications are in the order of 30 pN, with typical cantilever deflections in the order of nanometers.

An image of the magnetic stray field is obtained by slowly scanning the cantilever over the sample surface, in

a raster-like fashion. Typical scan areas are from 1 up to 200 μm , with imaging times in the order of 5–30 min.

Mode of Operation

The force F exerted on the tip by the stray field of the sample has two effects on the cantilever deflection. In the first place the cantilever end is deflected towards or away from the sample surface by a distance Δz :

$$\Delta z = F_z / c \quad [\text{m}] \quad [1]$$

where c is the cantilever spring constant in the z -direction (N/m) (units are given in square brackets in the equations). This deflection can be measured using soft, usually Si_3N_4 , cantilevers with spring constants in the order of 0.01–0.1 N/m . When measuring the deflection, the term *static mode* MFM is used.

For small deflections, the cantilever can be considered as a damped harmonic oscillator, which can be modelled by an ideal spring c (N/m), mass m (kg), and damper D (Ns/m) (Figure 2). When an external oscillating force $F_z = F_0 \cos(\omega t)$ is applied to the cantilever, the resulting displacement is harmonic as well, but has a phase shift for $\omega > 0$, $z = z_0 \cos(\omega t + \theta(\omega))$. This force can be applied directly to the end of the cantilever, for instance by electrostatic means. The most commonly used method is, however, to apply a force to the cantilever holder, by means of a piezo mounted underneath the holder.

Figure 1 Principle of magnetic force microscopy.

It is convenient to describe the relation between force and displacement in the Laplace domain. (The definition is commonly used in mechanical engineering textbooks $\hat{F}(s) = \int_{-\infty}^{+\infty} f(t)e^{-st} dt$.)

$$\frac{\hat{Z}}{\hat{F}} = \frac{1}{c + sD + ms^2} [m/N] \quad [2]$$

Using the natural resonance frequency ω_n and unitless damping factor δ ,

$$\omega_n = \sqrt{c/m} [2\pi/s] \quad [3]$$

$$\delta = \frac{D}{2\sqrt{mc}} = \frac{D\omega_n}{2c} \quad [4]$$

We can rewrite eqn [2] into

$$\frac{\hat{Z}}{\hat{F}} = \frac{1}{m\omega_n^2 + 2\delta\omega_n ms + ms^2} [m/N] \quad [5]$$

For underdamped systems ($\delta < 1$), this system has poles at

$$s_{1,2} = -\delta\omega_n \pm i\omega_n\sqrt{1 - \delta^2} = -\delta\omega_n \pm i\omega_d \quad [6]$$

The term $\omega_d = \omega_n\sqrt{1 - \delta^2}$ is referred to as the *damped natural frequency*. For MFM in dynamic mode, cantilevers with very small damping ($\delta \ll 0.01$) are used and $\omega_d \approx \omega_n$. In MFM it is customary to talk about the *quality factor* of resonance Q , instead of the damping factor. Q is proportional to the ratio between the energy

stored in the cantilever and the energy lost per cycle:

$$Q = 2\pi \frac{\text{Energy stored in cantilever}}{\text{Energy lost per cycle}} \\ = 2\pi \frac{\frac{1}{2}cz_0^2}{\pi D z_0^2 \omega_n} = \frac{c}{D\omega_n} = \frac{1}{2\delta} \quad [7]$$

For low-loss systems, the Q factor is approximately the number of oscillations required for a freely oscillating system to fall off to $e^{-2\pi}$ of its original energy. This is usually difficult to measure. Damping causes a widening of the resonance peak. The quality factor can therefore be more easily extracted from the width of the resonance at half the maximum amplitude $\Delta\omega$.

$$Q = \frac{\omega_n}{\Delta\omega} \quad [8]$$

Using Q eqn [5] becomes:

$$\frac{\hat{Z}}{\hat{F}} = \frac{1}{m\omega_n^2 + \frac{\omega_n m}{Q}s + ms^2} [m/N] \quad [9]$$

From eqn [9] we can calculate the amplitude z_0 of the cantilever vibration when driven at a frequency ω (eqn [1])

$$z_0 = \frac{F_0/m}{\sqrt{(\omega_n^2 - \omega^2)^2 + (\omega\omega_n/Q)^2}} \quad [10]$$

and the phase shift θ between the force and the deflection

Figure 2 The cantilever can be modelled as a damped harmonic oscillator.

Figure 3 A change in the magnetic force on the tip results in a change in resonance frequency of the cantilever, which can be detected in different ways.

(also see **Figure 3**):

$$\theta = \tan^{-1} \left(\frac{\omega \omega_n}{Q(\omega_n^2 - \omega^2)} \right) \quad [11]$$

In MFM, the force on the magnetic tip increases when it approaches the sample, so it is as if there is a second spring with a spring constant of $\partial F / \partial z$ attached to the cantilever. In the case that the cantilever deflection is so small that $\partial F / \partial z$ can be considered a constant, this results in a change in natural resonance frequency $f_n = \omega_n / 2\pi$ of the cantilever:

$$f'_n = f_n \sqrt{1 - \frac{\partial F_z / \partial z}{c}} \quad [\text{Hz}] \quad [12]$$

$$\Delta f = f'_n - f_n \approx -\frac{f_n}{2c} \frac{\partial F_z}{\partial z} \quad [\text{Hz}] \quad [13]$$

The approximation is accurate for $\Delta f \ll f_n$, which is always the case in MFM. Note the sign of Δf . In the above equations it is assumed that the positive z -direction is pointing away from the surface. When the tip is attracted toward the sample, the force therefore is *negative*, and the force derivative is positive. So for *attracting* forces, the resonance frequency of the cantilever *decreases*. Please note that eqn [12] is valid only for small vibration amplitudes. When $\partial F / \partial z$ cannot be considered constant, the vibration contains higher harmonics and is more elaborate, and numerical methods are needed to calculate the resonance frequency shifts.

Measurement of the resonance frequency of the cantilever is known as *dynamic* mode MFM (indicated by *frequency* in **Figure 3**). In this mode the cantilever is usually forced to resonate at an amplitude of 10–30 nm, so that an accurate detection of the very small frequency shifts is possible (typically 3 Hz on 80 kHz). In this mode a control circuit is needed, which matches the beat frequency of the actuator that drives the cantilever (e.g. a piezo), with the actual resonance frequency. Very often a phase-locked loop (PLL) circuit is used, which keeps the phase difference between the driving signal and the measured deflection of the cantilever at approximately 90°. This control circuit adds additional noise to the measurement signal. For small signals it is therefore sometimes preferable to fix the frequency of the driving signal to f_n and measure the phase difference between the driving signal and the measured cantilever deflection (indicated by *phase* in **Figure 3**). The phase shift, which is in the order of a few degrees, strongly depends on the damping of the cantilever, which in turn is a function of many parameters. The phase signal is therefore not really suitable for quantitative analysis.

An even simpler dynamic detection mode is to drive the cantilever off-resonance. A change in resonance frequency will result in a change in the vibration amplitude (*amplitude* in **Figure 3**). Even though this amplitude mode

works fine for atomic force microscopy (AFM), it gives very poor results for MFM because the amplitude variations are small compared to the noise. Moreover, the response of the cantilever to a change in a force is slow when the quality factor of resonance is high, which is for instance the case in a vacuum. Therefore, this mode is not used very often.

Fundamentally there is no difference in sensitivity between the static mode and the dynamic mode, because both modes use the same measurement geometry. Because of low frequency noise such as drift, the dynamic mode often gives better results, however.

Image Formation

To calculate the force on the magnetic tip, one has to start with the calculation of the energy U of the sample system. The gradient of this energy then gives the force vector. For MFM the interest is in $\partial U / \partial z$.

There are two ways to calculate U . One can calculate either the energy of the magnetic tip in the presence of the sample stray field or the energy of the magnetic sample in the presence of the tip stray field. In both cases, it is necessary to integrate the inner product of magnetic field and magnetization over the area where the magnetization is not zero:

$$U = -\mu_0 \int_{\text{tip}} \vec{M}_{\text{tip}} \vec{H}_{\text{sample}} dV = -\mu_0 \int_{\text{sample}} \vec{M}_{\text{sample}} \vec{H}_{\text{tip}} dV \quad [14]$$

Which method is more convenient depends on the problem which is to be analysed. One usually takes that form for which the stray field calculation is more easy to perform.

When discussing image formation and resolution, it is convenient to do that in the spatial frequency domain, a method commonly used in magnetic recording theory. The sample magnetization $\vec{M}$ in the sample plane (x, y) is decomposed into its Fourier components, leaving the z component untransformed:

$$\hat{M}(k_x, k_y, z) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} M(x, y, z) e^{-i(xk_x + yk_y)} dx dy \quad [15]$$

The relation between the wavelength of a certain component λ and the Fourier components is

$$k = (k_x, k_y) \quad [16]$$

$$k_{x(y)} = \frac{2\pi}{\lambda_{x(y)}} \quad [17]$$

The stray field of the sample generated by this magnetization distribution can be calculated by means of a Laplace transform. For a thin film with thickness t , one

can obtain with some patience,

$$\begin{pmatrix} \hat{H}_x(k_x, k_y, z) \\ \hat{H}_y(k_x, k_y, z) \\ \hat{H}_z(k_x, k_y, z) \end{pmatrix} = \begin{pmatrix} -ik_x/|k| \\ -ik_y/|k| \\ 1 \end{pmatrix} \frac{1}{2} (1 - e^{-|k|t}) e^{-|k|z} \hat{\sigma}_{eff}(k) \quad [18]$$

where $\hat{\sigma}_{eff}(k)$ is an *effective* surface charge distribution. It expresses the property of the Laplace transformation that the stray field at height z above the sample surface is fully determined by the stray field at height $z=0$. The effective surface charge distribution can be seen as a sheet of charges at the sample surfaces, which causes the same stray field as the more complex charge distribution within the sample itself.

For a sample with perpendicular magnetization ($M_x=0$, $M_y=0$), $\sigma_{eff}(x, y)$ simply equals the surface charge density σ .

$$\hat{\sigma}_{eff}(k) = \hat{M}_z(k) = \hat{\sigma}(k) \quad [19]$$

For a sample with an in-plane magnetization ($M_z=0$), only volume charges $\rho(x, y)$. If the magnetization is constant over the film thickness ($\partial M_x/\partial z=0$, $\partial M_y/\partial z=0$), the effective surface charge distribution becomes

$$\hat{\sigma}_{eff}(k) = -\frac{ik}{|k|} \cdot \hat{M}(k) = \frac{\hat{\rho}(k)}{|k|} \quad [20]$$

For more complex situations, every magnetic charge in the sample has to be transformed, which results in rather lengthy expressions, and this method loses its power. In that case it might be easier to calculate the stray field from the tip.

Assuming a known effective surface charge distribution, the energy of the tip/sample system can now be calculated by combining eqns [14] and [18]. The only thing left unknown is the magnetization distribution in the MFM tip, which can be very complex. The discussion will be restricted, however, to the bar type tip with a defined magnetization fixed along the z -axis (**Figure 4**), in the first place because this is the ideal MFM tip shape and in the second place because it results in very illustrative closed-form equations. The procedure to obtain the force F_z involves a simple integral of the stray field over the rectangular tip volume, and taking $\partial U/\partial z$:

$$\begin{aligned} \hat{F}_z(k, z) = & -\mu_0 M_t \cdot b \operatorname{sinc}\left(\frac{k_x b}{2}\right) \cdot S \operatorname{sinc}\left(\frac{k_y S}{2}\right) \\ & \times (1 - e^{-|k|b})(1 - e^{-|k|t}) e^{-|k|z} \hat{\sigma}_{eff}(k) \quad [21] \end{aligned}$$

where M_t is the tip magnetization (A/m), $b \times S$ the tip cross section, b the tip height, t the film thickness, and z the tip/sample distance (all in m) ($\operatorname{sinc}(x) = \sin(x)/x$). This relation between the force and the effective surface

magnetization is often called the *tip transfer function* (TTF).

Although eqn [21] is complex, it is not difficult to understand. It can be seen that the force is proportional to the tip magnetization and the magnetic charge density (σ) in the sample, combined with a number of geometrical loss factors. For most situations in magnetic data storage research, the films under investigation are thin and the film thickness loss term $(1 - e^{-|k|t})$ will dominate over the tip height term $(1 - e^{-|k|b})$. If one further assumes that the tip cross section ($b \times S$) is much smaller than the smallest features of the charge distribution in the film, gets a very simple expression for the TTF:

$$\hat{F}_z(k, z) = -\mu_0 M_t b S (1 - e^{-|k|t}) e^{-|k|z} \hat{\sigma}_{eff}(k) \quad [22]$$

This approximation can be called the *monopole* approximation, because it is assumed that all magnetic charges ($M_t b S$) are located at one point at the end of the tip, and that the other charges are very far away from the sample surface. The only loss terms that remain are the film thickness loss and the tip-sample distance loss, which usually is dominant. This immediately shows that for a good signal-to-noise ratio (SNR) in the image, the tip-sample distance has to be as small as possible.

When the details in the image start to approach the tip dimensions, the sinc functions have to be considered as well. For this bar-type tip, the force becomes zero when the wavelength of the surface charge distribution equals the tip size. This is analogous to the situation in magnetic recording, where at the *gap zero* the bit size is half the gap size of the recording head.

The force calculated in eqn [21] is measured by means of a cantilever deflection or change in resonance frequency. For the latter case, $\partial F_z/\partial z$ has to be calculated,

Figure 4 The ideal MFM tip has a bar shape and a magnetization fixed along its axis.

which in the Fourier domain is simply:

$$\frac{\partial \hat{F}_z(k, z)}{\partial z} = -|k| \hat{F}_z(k, z) \quad [23]$$

Typical examples of tip transfer functions (TTFs) for the static and dynamic mode and the resulting deflection and resonance shift, calculated from eqns [1] and [13], are given in **Figure 5**.

In this case a sample is considered with perpendicular magnetization and only magnetic surface charges, using the parameters from **Table 1**.

Instrumentation

The scope of this contribution does not allow for an exhaustive discussion of scanning probe microscope instrumentation. When using MFM or making decisions on the type of instrument to be used, some background information can be useful. In scanning probe instrumentation, the following subsystems can be recognized:

Probe The force on the magnetic tip is detected by means of a cantilever and a displacement sensor. The tip and cantilever will be discussed in detail in the section 'Tips', because the tip size obviously determines the ultimate resolution of the MFM. But this resolution can be

obtained only if the detection system is capable of measuring the very small deflections of the cantilever. Nowadays, mostly optical displacement sensors are used in high-resolution MFM, such as beam deflection systems or various types of interferometers. The beam deflection system is very robust and easy to align, but calibration of the sensor is possible only by indirect methods, such as calibration grids. The interferometer, however, is more difficult to align, but can be easily calibrated with respect to the laser wavelength. By using a fiber interferometer, the active size of the interferometer can be made extremely small, which is beneficial to the instrument stability. Whether the beam deflection or interferometer detection system is more sensitive depends very much on the implementation, but in principle the interferometer is a factor of 4 more sensitive. The detection limit is estimated to be as low as $10^{-15} m\sqrt{Hz}^{-1}$.

Positioning The positioning system brings the sample close to the tip (coarse positioning) and scans the tip over the sample area to obtain an image (fine positioning). The coarse-positioning system has the difficult task to achieve millimeter displacements with a stability better than 1 nm (when switched off). Ordinary manual or motorized screw positioners are used very often, sometimes in combination with levers. These systems suffer from drift: it can sometimes take hours before the displacement relaxes. Hysteresis is also a big problem. For vacuum systems (see next section), these screw positioners are not really useful since they require greasing, although some vacuum compatible systems do exist. Therefore, recent microscope designs resort to the use of piezo-actuated stepper actuators. Principles such as slip-stick, inertia and walking-beetle motions are used. The big advantage of these systems is that they are extremely stable once switched off.

The fine-positioning system has the difficult task to achieve an as big as possible scan range with sub-nanometers stability, and, on top of that, scan as fast as possible. For speed and stability it is advantageous to use a small scanner, but of course this is contradictory to the scan range requirement. In most microscopes so-called tube scanners are used. The major disadvantage of the

Figure 5 Tip transfer functions for a typical situation (**Table 1**).

Table 1 Parameters used to calculate the tip transfer functions shown in **Figure 5**

M_t	Tip magnetization	1422 kA/m
b	Tip thickness (coating thickness)	20 nm
s	Tip width	100 nm
h	Tip length	1 μm
M_s	Sample saturation magnetization	295 kA/m
t	Sample thickness	70 nm
z_0	Tip-sample distance	20 nm
c	Cantilever spring constant	0.01 (3) N/m
f_n	Cantilever resonance frequency	7 (75) kHz

Note: Values in parentheses are for the dynamic mode curves.

tube scanner is the coupling between the xy - and z -motion because the sample is tilted as well as translated.

Housing Although seemingly trivial, the environment in which the MFM instrumentation is mounted is of crucial importance to the image quality. The MFM works at extremely small tip-sample distances of 30 nm and less, but the tip never touches the sample surface. The mechanical path from tip to sample is several centimeters, six to seven orders of magnitude larger than the tip-sample distance. Therefore, the MFM is extremely sensitive to temperature variations, mechanical and acoustic vibrations and air flow. For high resolution the MFM is mounted on a vibration isolation table, in an environment which shields acoustic noise and air flow. Air-operated instruments are put in noise isolation cupboards, which enclose both the MFM and the vibration isolation table. To eliminate electromagnetic noise, the cupboard can be equipped with wire mesh to provide a Faraday cage. Sometimes ionizing units are mounted inside the cupboard to prevent static charge on the sample.

The ultimate acoustic noise isolation is obtained when the MFM is mounted in vacuum. A vacuum environment has many other important advantages. Damping of the very small cantilever is dominated by impingement of air molecules, which counteracts cantilever movement, and squeezing of air between the cantilever and the sample. The quality factor of resonance Q goes up by several orders of magnitude when the air is removed. This increase in quality factor strongly increases the instrument sensitivity, and therefore the resolution. Next to this, Brownian motion of the air molecules excite the cantilever as well and cause additional noise. Finally, the vacuum removes a large part of the gasses which stick to the sample surface, such as water. Especially the highly mobile molecules on the surface cause a problem, since they move toward the tip and form a meniscus, which pulls the tip into the sample. A vacuum of about 0.1 Pa (10^{-3} mbar) is sufficient to benefit fully from the effect of vacuum. Care must be taken, however, that the pressure is not too high and conditions for electric breakdown between the piezo electrodes are optimal for pressures between 1 Pa and 40 kPa (10^{-2} mbar and 0.4 bar). Since 1 Pa is difficult to reach with a rotary pump only, two-stage pumping systems are therefore almost a necessity.

Control The actual acquisition of an image requires a complicated control system, which takes care of tip sample positioning, both for scanning and for controlling the tip-sample distance, data acquisition and visualization, and possibly other control loops such as phase locking in dynamic mode measurements. With the gradual progress in digital signal processing (DSP), more and more tasks are being taken over by digital control systems. (This is how one of the biggest scanning probe microscope manufacturers got its name.)

Still high-quality analog electronics, such as the pre-amplifiers and high-voltage amplifiers for the piezos, are crucial and should not be neglected.

In the design of control electronics, two issues play an important role. First of all the noise caused by the control systems should be minimal. This means that high-quality components, such as powerful DSPs and low noise, high bandwidth DA converters, have to be used. As a result, for microscopes operated in air, the price of the control system usually equals that of scanning probe microscope hardware. In the second place, the control system should provide a user-friendly interface to the microscope system with a lot of flexibility in scanning modes and parameter tuning.

Tip-Sample Distance Control

There are at least two reasons why the measurement and control of the tip-sample distance is required. In the first place one wants to be as close as possible to the sample surface to obtain high resolution. Sample tilt, drift in the microscope positioning, and surface roughness will cause a variation in tip-sample distance over the image, and one can never get closer than the highest point on the surface. In the second place one will get a stronger contribution from nonmagnetic forces as one approaches closer and closer to the sample, and topographic information will be superimposed on the image. If the tip-sample distance is constant, the contribution of those forces will be more or less constant as well, and a topography-free image is obtained.

There are various ways to achieve constant tip-sample distance, all differing in complexity, precision, and stability. In the following sections, these approaches will be positioned in a structure as in **Figure 6**. Probably the ideal situation would be to use a *dedicated detector*, optimized for tip-sample distance measurement. STM seems to be a good candidate, because it will enable the control of the tip-sample distance with Å precision. The disadvantage might be that one only gets reasonable tunnelling currents at very low tip-sample distances, too low to allow for sufficiently soft cantilevers in static mode MFM or for sufficiently large vibration amplitudes in dynamic mode MFM. In the future, STM control might become an option, however. At higher tip-sample distances, one can still use the STM technique, but then in the field emission mode. This requires higher tip-sample voltages, and the resolution will not be as good as in STM. Another option might be to measure the capacitance between the cantilever or tip and the sample.

All these options require complex integrated probes with bond pads and wires running down the cantilever. That is why currently practically all methods to measure the tip-sample distance use the *same detector* as the one

Figure 6 Different ways to control tip-sample distance.

used for measuring the magnetic force (beam deflection, interferometer, piezo-resistive etc.). Since the same measurement channel is used, it is necessary to multiplex the magnetic and topographic signals. Multiplexing can be done in the time domain. This is the most commonly used method because it allows one to use AFM to measure the tip-sample distance. Time multiplexing can be done on various scales:

- Image-by-image** An example of this method is the real-time plane fit (for instance used in control systems manufactured by RHK), which is often used in static mode MFM. First an AFM image of the surface determines the slope of the image. Then one adds a correction signal to the z -piezo and makes sure that the AFM image appears flat: the average tip-sample distance is constant. More sophisticated systems use a polynomial fit to the surface in which bowing is taken into account. This is especially useful for large range scans using tube scanners. In principle, it is not necessary to measure the complete AFM image; depending on the order of the polynomial just a few strategically placed scanlines are sufficient. A big advantage of this mode is that there is no contact between the tip and the sample during image formation. Especially for soft magnetic samples, in which the domain image is easily disturbed by the MFM tip stray field, this mode has an advantage over the other two time-multiplexing modes discussed in this section.

In principle, the plane-fit method can be extended to measuring a complete AFM image and does the distance control on a pixel-by-pixel basis, but instrument drift during the time it takes to scan an image has to be less than the distance between the pixels. This type of accuracy is found only in low-temperature microscopes.

- Line-by-line** This method is called LiftMode by Digital Instruments and is used with dynamic mode MFM. Every line in the image is scanned twice. The first scan is in tapping mode AFM with amplitude detection (see the section Mode of Operation). The traced topography is stored in memory and used to

control the tip-sample distance in the subsequent MFM trace, using phase or frequency detection. Since the time per line trace is relatively short, this method works quite well. Moreover, the topographic and magnetic information are obtained simultaneously which makes mapping of topographic features onto the MFM image very easy. The method is less suitable for static mode AFM/MFM, because then very soft cantilevers are needed which snap into the sample. To ‘unsnap’ the cantilever, the z -piezo has to be withdrawn over quite a distance (sometimes more than a micrometer). Piezo-hysteresis and nonlinearity then make it difficult to approach the sample accurately again.

- Pixel-by-pixel** This mode can be compared with the spectroscopy mode used in STM. For every pixel a force distance measurement is made (F_z as function of z). From the snap-in or contact point the tip-sample distance can be calculated, and a map of the magnetic force for different tip heights can be made. Of course, this mode is very slow and suffers heavily from $1/f$ noise. The extra information obtained is useless; one can easily calculate the MFM signal at a height z from images taken at lower height. One might think that by scanning at different tip-sample distances one can determine the volume distribution of the magnetic charges in the sample, but the nature of the magnetic stray field simply prohibits that. This mode, however, does allow for the smallest tip-sample spacing, especially in static mode MFM.

The last branch in **Figure 6** is the reciprocal to time multiplexing, which is frequency multiplexing. This means that topographic and magnetic information is measured in different frequency bands. To achieve this, it is necessary to modulate the magnetic force or the force responsible for the topographic signal (or both). Contact mode AFM is not possible in this frequency multiplexing mode, because the magnetic forces cannot be measured simultaneously. So one needs a noncontact measurement of the topography. Noncontact mode AFM might be a possibility, but has never been used before. It will be very hard, if not impossible, to be modulate the forces measured during AFM (such as van der Waals forces), so the magnetic force has to be modulated. This can be achieved by applying an external magnetic field which modulates the magnetization in the tip. The same field would also act on the sample, however, and probably only hard magnetic samples can be measured.

Another way to measure the topography in non-contact mode is to use an electric field. This has been demonstrated by Schonenberger et al., who applied a modulated voltage between the cantilever and the sample. The frequency of modulation is well below the resonance frequency of the cantilever, so that the cantilever

will start vibrating. The amplitude of vibration is a measure for the tip-sample distance and is kept constant. This method can be applied to static mode as well as dynamic mode MFM. In principle, the method is similar to the measurement of the tip-sample capacity, the electric force and the change in capacity being related by

$$F_{el} = \frac{\partial C}{\partial z} V^2 \quad [24]$$

Tips

Ideal Tip Shape

Most scanning probe microscope tips are pointed and very sharp: the STM tip and AFM tips are atomically sharp, and most SNOM tips are tapered optic fibres. One might therefore assume that an MFM tip should also have the shape of a sharp needle. Techniques such as STM, AFM, and SNOM, however, measure very short range effects, whereas MFM measures long-range magnetostatic forces. (The same holds for electric force microscopy (EFM) and electrostatic forces.) In STM and AFM only the last atom determines the signal, but in MFM a much larger part of the tip takes part in the image formation. Therefore, the optimum tip shape is not a sharp needle but a bar or a cylinder with a flat front end, analogous to a hard disk head for perpendicular magnetic recording.

The fact that the bar shape is the optimum shape for MFM can perhaps be most easily understood by considering the magnetic charge distribution in a tip with an ideal uniform magnetization (see **Figure 7**). In a bar-type tip, all magnetic charges are located at the front surface of the bar, and as close as possible to the sample surface. Therefore, all magnetic charges contribute equally well to the signal. In a pointed MFM tip, the charge is distributed over the complete tip. The charges located further away from the sample still contribute to the

signal, but their effect is stronger at longer wavelengths. If the maximum signal of a pointed tip and a bar-type tip is set equal, the bar-type tip will perform better at high spatial frequencies, and therefore show a better resolution. Of course, when the wavelengths approach the gap zero of the bar tip, the pointed tip performs better. But one can always tailor the bar-type tip in such a way that this happens at wavelengths above the critical wavelength, as indicated in **Figure 7** on the right. One can argue that one may allow the pointed tip to have higher signal at low spatial frequencies by increasing the tip length. This, however, does not significantly increase the signal at high spatial frequencies. In all cases, the signal close to the critical wavelength will be highest for the bar-type tip.

Realistic tips will not have a flat front end, but rather a more rounded shape. Saito et al. have shown that for tip dimensions above 5 nm, an elliptical rather than flat tip performs better because of the absence of the gap zero.

The optimum tip shape can be easily decided, but its construction is a much more difficult matter. When realising MFM tips, one needs such small feature sizes that one cannot rely on conventional lithography (as used in semiconductor industry). Instead one has to use tricks to obtain such small dimensions, and one enters the area of nanotechnology. The first scanning probe microscope tips were hand made in a one-by-one fashion. Still the best tips available today are made by hand. The batch-fabricated Si and SiN tips, however, strongly improved the ease of use of the MFM. In the following section a number of MFM tips have been briefly mentioned, starting with hand made tips and continuing with batch-fabricated tips.

Hand Made Tips

The first MFM cantilevers were very thin Co or Ni wires which were etched down to a sharp point. The wires were bent around a razor blade edge, and the laser spot was

Figure 7 Sharp-point versus bar-type MFM tips. The width of the base of the triangular tip is adjusted in such a way that the maximum signals of both tips are equal.

deflected from the resulting 'knee' – a far from stable operation. The tips obtained this way were, however, not very sharp and contained a lot of magnetic material. Much better resolution could be obtained with tungsten tips coated with a magnetic layer from the side. The resulting magnetic thin film was, however, not always smooth, due to the surface roughness on the tungsten point caused by the etching process.

A much smoother tip could be obtained by using contamination needles, which were at that period already used for AFM. These contamination needles were grown in an SEM which was accidentally or deliberately contaminated with organic gasses. On the side of these carbon tips, a thin magnetic layer is deposited. Some call these electron beam deposited (EBD) tips, but to avoid confusion with electron beam evaporation, which is a layer deposition technique, others call these electron beam induced deposited (EBID) tips. Especially the tips made by Skidmore et al. are impressive, with a tip radius of less than 7 nm. Strangely enough, the resolution of the images is not better than obtained with conventional tips. Instead of depositing a layer on the side of the EB(I)D tip, one can also use the contamination as an etch protection mask. In this way one can leave a tiny disk of magnetic material at the top of an AFM tip. This MFM tip does not have the ideal shape for high resolution, but can for instance be used in those situations where a low tip switching field is necessary (**Figure 8**).

The arrival of the focussed ion beam (FIB) instrument opened new possibilities for MFM tip preparation. The two techniques known to the author start with a magnetic coating on a commercial AFM cantilever. Folks et al. start with a commercial MFM tip, and then FIB etch a small

hole at the apex of the tip. The tip is then magnetised in-plane (parallel to the cantilever), so that magnetic charges occur at the edges of the tip. In this way one obtains an in-plane tip which is sensitive only to stray fields parallel to the sample in the direction of the tip magnetization (x - or y -direction). In general one would like to measure the z -component, from which the x and y components of the fields can easily be derived. Such a tip is prepared by Phillips, who starts with a thin Co film on a commercial AFM cantilever, and then etches away the unnecessary material. In this way an 8 μm long, 50 nm wide needle could be prepared.

Coating of AFM Tips

The workhorse of the MFM cantilevers is an Si batch-fabricated cantilever with a tip optimized for AFM, which is coated with a magnetic material. There is a large variety in magnetic coating and it is virtually impossible to give exhaustive list. One can, however, indicate different categories. The most common magnetic coating is an alloy based on Co with additions such as Cr and Pt, pioneered by the work of Grütter et al. These alloys are often derived from hard disk recording layer materials and have a high coercivity. The high coercivity makes the tip resistant against reversal by the medium stray field. To achieve a high coercivity, the material is prepared in such a way that one gets magnetically separated grains. The exact location of these grains on the tip apex varies from tip to tip, which explains why some tips have higher resolution than others. Companies sell tips with different coercivities and film thicknesses (and give them

meaningful names such as ‘high coercivity tip’ or ‘low moment tip’).

For some applications, the coercivity of the layers on the tips is not high enough, for instance when measuring stray fields from recording heads or permanent magnets. In that case an alternative can be found in very soft magnetic coatings which switch in very small external fields. As a result, however, the tip is always attracted and one loses information on the polarity of the field. Materials used are, for instance, Co, NiFe, Fe, and granular Fe(SiO₂) films.

The perfectly soft MFM is diamagnetic, such as a Pt-coated tip. Of course the magnetic moment is much lower than in ferro- or superparamagnetic tips, and the signal is very low.

Although magnetically coated AFM tips are widely used in MFM, they are a bad approximation to the ideal tip shape. In the following section, a new method is discussed to realize batch-fabricated tips, in a method optimized for MFM.

Tip Planes: The CantiClever Concept

A magnetic tip that is suitable for high-resolution MFM should have lateral dimensions in the nanometer regime. One would like these dimensions to be controllable and variable to be able to customize the MFM tip for different types of measurements or samples. The CantiClever design discussed in this section accomplishes this by defining both lateral dimensions by thin film deposition techniques. The magnetic tip is made by deposition of magnetic material on the side of a free-hanging, very thin layer called the tip plane. The width and thickness of the magnetic tip are defined by the thickness of the tip plane and the magnetic layer respectively. The length of the tip is defined using photolithography. A schematic drawing of the structure is shown in Figure 9.

Such a structure is very difficult to make, however, when the approach used to make conventional cantilevers is used. During fabrication, the conventional cantilevers are situated such that the oscillation direction is perpendicular to the surface of the substrate. Using this approach would need the very thin tip plane to be

Figure 9 The cantilever with the tip plane.

fabricated as a freestanding layer perpendicular to the substrate surface. Instead, the free-hanging tip plane is made in a completely new approach. During fabrication, the cantilevers are tilted 90° compared to the conventional cantilevers, creating a lateral oscillating cantilever with its oscillation direction parallel to the substrate surface as shown in Figure 10.

This approach makes the fabrication of the cantilever more difficult compared to conventional cantilevers, but also enables precise control over the cantilever resonance frequency. The resonance frequency is given by eqn [13]:

$$f_0 = \frac{1}{2\pi} C_0^2 \frac{t}{l^2} \sqrt{\frac{E_{Si}}{12\rho_{Si}}} \quad [25]$$

where C_0 is the eigenvalue of the system corresponding to its fundamental frequency, having a value of 1.875, t the thickness of the cantilever, l its length, E_{Si} the Young modulus of the silicon (150 GPa) and ρ_{Si} its density (2330 kgm⁻³).

Figure 10 Tip plane on the cantilever for both cantilever orientations. Left: conventional approach with horizontally vibrating cantilever. Right: new approach with laterally vibrating cantilever.

Figure 11 Cantilever with tip plane and detail of the tip plane (inset).

In contrast with the fabrication method used for conventional cantilevers, this approach allows the dimensions of the cantilever which determine the resonance frequency, the cantilever thickness t and the length l , to be controlled and varied as both are defined parallel to the substrate surface. Standard deposition and etching techniques can be used to define the tip plane, as it is also oriented parallel to the substrate surface. The result is a reproducible manufacturing process that incorporates both the cantilever and the magnetic tip and allows for batch fabrication of the probes. An SEM photograph of a CantiClever is shown in **Figure 11**. The free hanging tip plane and the smooth sides of the cantilever itself can clearly be distinguished.

Introduction

Superparamagnetic nanoparticles play an important role as contrast agents for visualizing disease, treatment, and biological response with magnetic resonance imaging (MRI). In these applications, particle location is visualized indirectly by exploiting particle magnetism to influence the MRI signal detected from nearby water protons. This has the advantage of allowing simultaneous viewing of anatomy but confounds quantitative determination of particle amounts because MRI signal generally varies from tissue to tissue, and depends on a host of other factors besides nanoparticle concentration.

Ongoing progress in the synthesis of superparamagnetic nanoparticles and their use as drug delivery vehicles increases the need for a quantitative imaging platform that not only measures nanoparticle location but also amounts. **Figure 1** shows the basic structure for a novel carrier that is designed for the systemic administration of water-insoluble anticancer drugs while simultaneously allowing for imaging. Current interest in these possibilities is so widespread that related work is in the top five most read articles of *Molecular Pharmaceutics*. Nevertheless, with MRI, only a qualitative understanding of drug delivery and clearance can be attained. And even then, images are not always readily interpreted since nanoparticles like those shown in **Figure 1** are typically more effective at destroying MRI signal than enhancing it. Consequently, their location is usually identified by reduced image intensity that can be difficult to distinguish from normal tissue heterogeneity. To reduce ambiguity, magnetic particle detection with MRI requires long acquisition times and relatively high particle concentrations.

In pharmaceutical research, there is ongoing interest in inhaled drug delivery since it is often more efficient than the traditional oral route. Monitoring nanoparticle distribution and clearance in the lung is also important for understanding the potential health risks that might be associated with inhaled pollutants. Unfortunately, proton MRI is extremely ineffective in the lung due to low water

content and the severity of susceptibility broadening at air-tissue interfaces. To overcome these problems, recent inhalation work, illustrated in **Figure 2**, exploits ^3He gas MRI for visualizing superparamagnetic nanoparticle deposition. Like proton MRI, however, particle detection is still indirect so results only provide a qualitative picture of inhaled deposition patterns. Moreover, the indirect approach necessarily reduces detection sensitivity and tissue-dependent performance complicates any study of biodistribution if inhaled material translocates from the lung to other body regions.

In recognition of MRI's limitations, scientists from Phillips Research in Germany have recently developed a new approach for nanoparticle visualization that they call magnetic particle imaging (MPI). Unlike MRI, which relies on indirect nanoparticle detection, MPI utilizes the nonlinear behavior of superparamagnetic nanoparticle magnetization to directly detect their location and amount with high sensitivity and resolution. Although not yet commercially available, MPI is well suited for preclinical research, diagnostic imaging, and quantitative dosimetry for drug development and toxicology testing. Here, its basic principles are reviewed, factors affecting sensitivity and resolution are highlighted, and potential MPI performance is examined.

Basic Principles

Superparamagnetic nanoparticles typically have diameters less than a hundred nanometers (nm) and usually consist of ferromagnetic material such as iron, cobalt, or nickel. In biomedical applications, iron oxides such as magnetite (Fe_3O_4) or maghemite (Fe_2O_3) are attractive because they are relatively well tolerated in the body and their surfaces are readily coated for enhanced biocompatibility and site-specific binding. Below a critical diameter of ~ 30 nm for magnetite, ferromagnetic behavior becomes thermally unstable at room temperature. In this so-called superparamagnetic regime, thermal energy is sufficient to change the direction of each nanoparticle's ferromagnetic moment so no net magnetization ($\mathbf{M}$) is observed from an ensemble in the absence of an external magnetizing force field ($\mathbf{H}$). When an external field is applied, each particle's intrinsic ferromagnetic moment aligns with the applied field to collectively form a net magnetization approaching ferromagnetic strength.

When superparamagnetic nanoparticles are exposed to a static magnetic field, competing magnetic and thermal forces determine the level of order. On one hand, thermal fluctuations randomize magnetic moment orientations, and on the other, the applied field increases alignment along its direction. Generally, competition between the two dictates a net magnetization ($\mathbf{M}$) that varies nonlinearly with the applied magnetizing force field ($\mathbf{H}$). In MPI, this nonlinearity is exploited by applying a periodic (ac) magnetizing force to induce a time-varying particle magnetization. The first panel on the left in **Figure 3** shows that upon Fourier transformation, this not only contains the characteristic frequency of the applied modulation (f_0) but also higher-order harmonics (Nf_0) that are then detected using an inductively coupled receiver. Since the third harmonic is typically the largest, it is commonly exploited for MPI signal detection.

Generally, signal localization can be understood by considering how harmonic response varies when a static magnetic field is superimposed with ac modulation. If the static field is strong, particle magnetization saturates. In this case, the right panel in **Figure 3** shows that no MPI signal is detected because particle magnetization is constant and no harmonics are generated. Conversely, in the absence of a static field, particle magnetization is free to respond and harmonic generation is maximized. To localize the MPI signal, these differences are exploited by generating a strong, linear, and static magnetic field gradient. Particles far away from the gradient origin then contribute nothing to the detected signal since they experience static fields that saturate their magnetization. Particles at the origin, however, produce maximum signal because the static field there is zero. Images are formed by moving the sample within the localizing field gradient, or conversely, by moving its origin through the sample volume.

Transceiver Design and Function

Every MPI system requires a transceiver circuit to generate and detect harmonics in nanoparticle magnetization. One possible configuration is shown in **Figure 4(a)**. The circuit comprises two halves that appear on either side of the dashed vertical line. Both sides share a common ground but are otherwise electrically isolated from one another. The left half functions as the transmitter and the right functions as the receiver. During operation the transmitter is used to generate a time-varying magnetic force field ($\mathbf{H}$) that oscillates with a characteristic frequency f_0 . The receiver side is then used to detect the magnetization's third harmonic at $f_3 = 3f_0$. In practice, the oscillating $\mathbf{H}$ -field produced by the transmitter is generated using a wire wound solenoid that surrounds the

Figure 3 Schematic illustration of signal detection and localization in MPI. Left panel: Signal detection uses an oscillating (ac) magnetic force field (H , red curve) and nonlinear nanoparticle magnetization (M vs. H , black curve) to produce a time-varying response (M vs. time, green curve) that not only contains the modulation frequency (f_0) of the applied ac modulation (H , red curve) but also higher-order harmonics (at $3f_0$, $5f_0$, etc.) that are detectable after a Fourier transform (green bars) of induced voltage in a surrounding detector coil. Right panel: Signal localization exploits the fact that harmonic generation is reduced if a strong static magnetic force field is superimposed with the ac modulation (H , red curve). sample and is represented by the resistor R_0 and inductor L_0 . The variable capacitors C_{T0} and C_{M0} tune and match the transmitter circuit to $50\ \Omega$ to ensure efficient power transfer. On the receiver side, C_{T3} and C_{M3} tune and match a concentric detection coil that is represented by the resistor R and inductor L .

Figure 4(b) shows a possible configuration for the transmitter (R_0 , L_0) and receiver (R , L) coils. The detector coil resides inside the transmitter solenoid and also surrounds the sample. The detector coil is composed of three small solenoids that are each wound on the same former and are separated along their symmetry axis. All are connected in series but the central coil has twice as many windings as each of the outer two. The central coil is also counter-wound as indicated by the winding directions depicted for the inductor L in **Figure 4(a)**. In practice, this minimizes inductive coupling between the transmitter and receiver coils, thereby improving electrical isolation. This is understood by considering what happens when the transmitter coil (R_0 , L_0) produces its time-varying H -field and the detection coil (R , L) is centered inside. In this case, the changing magnetic flux through each of the detector's three solenoids induces counter-rotating currents that cancel one another. Any harmonic distortion coming out of the amplifier used to drive f_0 is therefore canceled and does not contribute to the measured voltage at f_3 . Conversely the sample at the center of the detector coil (corresponding to the gradient origin) is more tightly coupled with the detector's middle solenoid than either of its outer two. The sample's time-varying magnetization at the center of the transceiver therefore induces a net voltage that is then measured by the receiver. In practice,

two LC traps are utilized for additional isolation since a small amount of residual coupling between the concentric transmitter and detector coils is typical. L_3 and C_3 form a parallel resonance at f_3 that attenuates harmonic distortion from the amplifier, whereas L_0 and C_0 form a parallel resonance at f_0 to protect the sensitive receiver from any residual transmitter voltage.

Sensitivity, Signal Attributes, and Detection Limits

Recent mathematical models of MPI performance describe how sensitivity varies with transceiver design, operation, and nanoparticle properties. **Figure 5** shows predicted variations with ac modulation frequency (f_0) and magnetite core diameter when nanoparticles in **Figure 1** are excited with an ac field of $10\text{ mT}\mu_0^{-1}$. Results highlight how sensitivity increases with modulation frequency and, that at any particular frequency, there is an optimal core diameter.

Sensitivity in **Figure 5** generally varies with $f_0^{3/4}$. A small advantage is therefore realized by operating at higher frequencies. In biomedical applications, the maximum allowable frequency is determined by safety guidelines that limit whole-body electromagnetic power dissipation to no more than 4 W kg^{-1} over any 15 min exposure. Under the conditions represented in **Figure 5**, this limit is exceeded at $\sim 28\text{ kHz}$ in humans. When imaging laboratory animals, higher frequencies can be used because electromagnetic power dissipation per unit body weight generally decreases with the square of

Figure 4 (a) Circuit diagram for a simple MPI transceiver. (b) Schematic illustration for possible coil and sample configuration. The sample (illustrated by the red sphere) is surrounded by a large, outer solenoid (L_0 , R_0) that is used for generating a magnetizing force field ($\mathbf{H}$) that oscillates at f_0 . The detector coil (L , R) resides inside the transmitter solenoid and is drawn with bold lines for clarity. The inset at the upper right shows that the detector coil is concentric with both the transmitter coil and sample. The inset at the bottom left shows a prototype detector coil that has a 10 mm diameter and is composed of 140 turns of copper wire that is 114 μm thick. In both insets the white crosshair represents the gradient origin if the coils were located inside an imaging system.

sample diameter. As a consequence, studies with rats and mice can be safely performed up to ~ 160 and ~ 300 kHz, respectively.

At any particular ac modulation frequency (f_0), **Figure 5** shows that there is an optimal core diameter. At low frequencies, larger particles are favored because their magnetization changes more steeply in weak magnetic fields and this causes stronger harmonics. However, as frequency increases, relaxation processes make it harder for a larger nanoparticle's magnetization to follow the ac modulation, and eventually, this damps its harmonic response more

Figure 5 Predicted sensitivity variation with transmitter frequency (f_0) and magnetite core diameter when nanoparticles in **Figure 1** are excited with an ac field of $10 \text{ mT } \mu_0^{-1}$. Relative sensitivity is displayed using a linear color scale and projections are based on recent mathematical models. Adapted from Ferguson RM, Minard KR, and Krishnan KM (2009) Optimization of nanoparticle core size for magnetic particle imaging. *Journal of Magnetism and Magnetic Materials* 321: 1548–1551.

severely than smaller counterparts. At any particular frequency, competition between both effects results in an optimal value.

Generally, strong size dependence means that sensitivity per unit mass decreases when there is a distribution of nanoparticle sizes about the optimal. Although core sizes other than optimal contribute to total mass, their harmonics are weaker; thereby, reducing mass sensitivity. To maximize mass sensitivity it is desirable to exploit nanoparticles with a narrow core-size distribution centered on the optimal.

An important attribute of MPI signal is that its strength varies linearly with nanoparticle amount, and is independent of whether nanoparticles are suspended in liquid, dispersed in tissue, or locked in a polymer matrix from larger micron-sized particles. This is illustrated in **Figure 6** where MPI signal collected with a homebuilt transceiver is shown. Signal was collected at 750 kHz (f_3) using an ac modulation of 250 kHz (f_0) and the transceiver design shown in **Figure 4(a)** and **4(b)**. Signal for ac modulation at f_0 is provided by an Agilent 33250A waveform generator and is amplified using an ENI 320L amplifier. Harmonic detection at $3f_0$ is then achieved using an Agilent ESA series spectrum analyzer.

The transceiver in **Figure 6** is designed to accommodate a 5 mm diameter sample tube. During signal measurements the sample tube resides inside the coil shown in the inset of **Figure 4(b)**. In recent work, mathematical modeling of MPI sensitivity is described for a comparable detector coil. The results in **Figure 7** show

Figure 6 (a) Homebuilt transceiver based on **Figure 4**. The white arrow points to the sample tube. (b) Signal calibration for commercial magnetic and fluorescent microspheres with diameters ranging from 1 to $2\ \mu\text{m}$ (Catalog # 19133–5, Polysciences, PA). Black shows detected MPI signal linearity (voltage in arbitrary units) and gray shows detected fluorescence signal after particles were digested. (c) MPI signal voltage for different microsphere masses before and after deposition in excised lung tissue. Results highlight that MPI signal linearity is tissue independent. (d) MPI signal power versus iron content in diluted FeridexTM IV solutions. Stock Feridex from the manufacturer (Advanced Magnetec, Cambridge, MA) comes as a liquid suspension containing nanoparticles with a mean hydrodynamic diameter of approximately 58.5 nm. Particle cores are aggregates of iron oxide crystals incompletely coated with dextran to facilitate biocompatibility.

Figure 7 Predicted signal-to-noise ratio per cubic meter of magnetite plotted as a function of core diameter (d) in nanometers. Projections are given for different transmitter frequencies (f_0). Results are from Ferguson RM, Minard KR, and Krishnan KM (2009) Optimization of nanoparticle core size for magnetic particle imaging. *Journal of Magnetism and Magnetic Materials* 321: 1548–1551.

how the signal-to-noise ratio per cubic meter (SNR_v) of magnetite varies with modulation frequency (f_0) and core diameter (d) when the strength for ac modulation is $10\ \text{mT}\ \mu_0^{-1}$, no averaging is performed, and data are collected with a 1000 Hz receiver bandwidth. With a commercial spectrum analyzer that requires a minimum of approximately 10 sampling points for Fourier transformation, this bandwidth would be achieved in a single sweep lasting ~ 10 ms. Under these conditions, predicted performance indicates SNR_v is $\sim 1 \times 10^{16}$ when the core diameter is ~ 15 nm and the modulation frequency is ~ 250 kHz. Consequently, an SNR of 5 only requires $5 \times 10^{-16}\ \text{m}^3$ of material, or ~ 2.6 ng of magnetite since its density is $5.25 \times 10^6\ \text{g m}^{-3}$.

Generally, MPI sensitivity scales inversely with the diameter of the detection coil. The detection limit for an 8 cm diameter coil used for imaging a live mouse would therefore be about eight times greater than for the 1.0 cm

coil modeled in previous work. This corresponds to ~ 20 ng of magnetite if an SNR of 5 is required. To put this in perspective, consider that high-field proton MRI at 11.7 T has been used to detect as little as 0.1 ng of magnetite in live mice when the total acquisitions last 1.5 h. In MRI, however, signal averaging occurs over the entire acquisition so results are equivalent to $\sim 540\,000$ MPI averages if each lasts just 10 ms. Given that the SNR increases with the square root of signal averages, MPI could then detect ~ 0.09 ng over an equivalent measurement time. Mass sensitivity with MPI is therefore similar to that achieved with high-field MRI. MPI, however, overcomes many of MRI's shortcomings. Moreover, with MRI, the detected 0.1 ng had to be localized in single cells for confident detection. Concentrations were therefore extremely high. With MPI, no such constraint exists. Consequently, if 20 ng were distributed inside a live mouse and no imaging was performed, so that signal from the entire mouse was collected, a measurable response could still be detected in ~ 10 ms. Taking the mouse volume to be ~ 50 ml, and noting that 1 ng of magnetite is ~ 4 pmol (4×10^{-12} mol), concentrations as low as ~ 1.6 nmol l $^{-1}$ should be detectable in just 10 ms! This is far below the detection limit for MRI and is more comparable to that achievable with radiotracers and positron emission tomography. For human studies, MPI's inventors have projected detection limits on the order of ~ 50 ng of magnetite. Considering they model a detection coil large enough for brain imaging, this detection limit agrees with the above sensitivity considerations.

Resolution, Gradient Requirements, and Imaging Performance

Pioneering work by MPI's inventors demonstrates that image formation can be achieved either by moving the sample through a static magnetic field gradient or by keeping the sample stationary and electronically moving the gradient origin. With either approach, resolution is approximately given by B_{AC}/G , where B_{AC} ($=\mu_0 H_{AC}$) is the strength of ac field modulation required to generate strong harmonics and G is the strength of the applied gradient used for localizing MPI signal. Given B_{AC} is typically about 10 mT, gradients on the order of 10 T m $^{-1}$ are required for 1 mm (10^{-3} m) resolution.

A distinct advantage of moving the gradient origin with electronically controlled currents is that it facilitates rapid imaging. This is illustrated in **Figure 8** where successive images of a rotating sample are collected at a rate of 26 images per second. Experiments, however, were performed using a small, highly concentrated sample with 500 mmol Fe per liter. This is approximately 1000 times higher than the maximum concentration in blood after administration of commercial contrast agents at FDA-approved doses (~ 500 μ mol l $^{-1}$). Moreover, imaging was performed using a very small sample and a field of view that was only 0.01 m on a side. Observed imaging performance in prior work is therefore not very representative of what might be achieved in biomedical research where lower concentrations are expected and imaging has to be done over a larger field of view.

Figure 8 Fast imaging of a small rotating sample. Each image required 39 ms to collect and every ninth in a series is shown for illustration. Simulation results at the right account for all known system and tracer properties. Reproduced from Gleich B, Weizenecker J, and Borgert J (2008) Experimental results on fast 2D-encoded magnetic particle imaging. *Physics in Medicine and Biology* 53: N81–N84, with permission of IOP Publishing Limited.

To examine possible imaging performance in small laboratory animals, it is helpful to focus on the use of sample translation for image formation. Although a cruder imaging approach than that used in **Figure 8**, it is conceptually simpler to understand, and as will be shown, is entirely feasible for preclinical research with rodents.

One possible magnet configuration for generating large gradients and exploiting them for imaging live mice is illustrated in **Figure 9**. It shows an expanded view of a permanent magnet assembly that consists of 8 magnetic disks and 12 magnetic rings. Each disk is 5.08 cm thick by 10.16 cm in diameter, and each ring is 2.54 cm thick with inner and outer diameters of 7.62 and 15.24 cm, respectively. All are made of N4017 neodymium-iron-boron (NdFeB) and are commercially available.

The disks depicted in **Figure 9** are all shown in their proper location and are arranged to form a magnetic quadrupole. This is desirable since resulting magnetic fields form closed loops that strengthen resulting gradients around the assembly's origin. To provide the greatest imaging resolution in the xy -plane, disk magnets are arranged as close as possible – while still leaving room in the middle for required transceiver coils. The depicted arrangement of disks forms a square bore that is 10.16 cm

on a side and is accessible along the imager's z -axis. In practice, this bore is large enough to accommodate a detection coil with an 8 cm diameter. During imaging, this would remain stationary inside the magnet bore and the mouse would be moved inside of it. MPI signal strength would then be logged at each position as the mouse is moved through the system's stationary field gradients.

For clarity, the rings in **Figure 9** are shown displaced along the z -axis. Two stacks are shown and each is composed of six individual rings that are positioned one-on-top-of-another with their magnetization in the direction indicated by bold arrows. To create the highest resolution along the z -axis, rings need to be moved toward the origin during construction so that the closest ring in each stack bumps up against the disks that comprise the quadrupole. In this configuration, the closest faces of opposing rings on opposite sides of the quadrupole are separated by ~ 10 cm. Although more rings could potentially be added to further strengthen gradients along the z -axis, improvements increase very slowly and are therefore not cost effective. This is because each additional ring must be added to the end of the stack – where its contributions at the origin are weakest.

Figure 9 Upper left: Expanded view of possible magnet configuration for rodent imaging. Calculated magnetic field strength ($\mathbf{B} = \mu_0 \mathbf{H}$) is shown for the xy - (upper right), xz - (lower right), and yz -planes (lower left). All magnetic field contours are specified in kilogauss (1 kG = 0.1 T) and xyz positions are in the coordinate system shown at the upper left.

Magnetic field simulations for the described assembly are also shown in **Figure 9**. The contour plots show that the calculated magnetic field strength ($\mathbf{B} = \mu_0 \mathbf{H}$) is zero at the center of the imaging system and increases in all directions away from this so-called sensitive point. Local field gradients around the sensitive point are found to be 12 T m^{-1} along the x -axis, 14 T m^{-1} along the y -axis, and 2.6 T m^{-1} along the z -axis. Generally, contours in the xz - and yz -planes are different because the rings break the symmetry of the quadrupole formed by the disks. This is easily seen if each stack of rings is imagined as a simple dipole. The dipole fields are then seen to point along the disk's magnetization on the y -axis but point in the opposite direction along the x -axis.

In the strong magnetic field gradients around the imager's origin, particle magnetization quickly saturates and is nonresponsive to the applied ac field. The point-spread function (PSF) shows explicitly how magnetization from different locations contributes to the detected MPI signal, and is calculated from the strength of its third harmonic. **Figure 10** shows the PSF along each axis when the ac field strength is $10 \text{ mT } \mu_0^{-1}$, the modulation frequency (f_0) is 250 kHz , and imaging is performed using 15 nm magnetite particles. The small negative lobes along the z -axis represent additional blurring from the ac field modulation along that direction. Without deconvolution, image resolution is traditionally defined by the width of the PSF. Along the z -axis, this is taken to be the distance between positive and negative zero-crossings. Since the PSF's along x - and y -directions have no lobes, resolution is more routinely defined by their full-width half-maximum. Using these conventions, expected resolution without image deconvolution is $\sim 2.0 \text{ mm}$ along the x -axis, $\sim 1.8 \text{ mm}$ along the y -axis, and $\sim 6.0 \text{ mm}$ along the z -axis. Numerical studies show that this resolution can

Figure 10 Calculated PSFs for 15 nm magnetite when the modulation field is $10 \text{ mT } \mu_0^{-1}$ and magnetic field gradients are generated with the magnet configuration shown in **Figure 9**. The dashed line defines spatial resolution along the z -axis, the solid line along the x -axis, and bold line along the y -axis. Adapted from Ferguson RM, Minard KR, and Krishnan KM (2009) Optimization of nanoparticle core size for magnetic particle imaging. *Journal of Magnetism and Magnetic Materials* 321: 1548–1551.

be further improved by (1) decreasing the strength of ac field modulation and (2) increasing particle size. Since both reduce sensitivity, compromises between signal strength and image resolution are required.

To describe in more detail achievable imaging performance in a live mouse, suppose the goal is to monitor the three-dimensional (3D) biodistribution of nanoparticles with an optimal 15 nm diameter core of magnetite. With an ac modulation of $10 \text{ mT } \mu_0^{-1}$ at 250 kHz , a 15 min imaging session would not exceed safety limits on electromagnetic power dissipation. If the mouse were imaged at a resolution of $2 \times 2 \times 6 \text{ mm}^3$ along the x -, y -, and z -axes, respectively, $15 \times 15 \times 15$ sample movements would be required to cover a rectangular field of view of $3 \times 3 \times 9 \text{ cm}^3$. For a detection limit of 20 ng , signal at each location requires $\sim 10 \text{ ms}$ to collect. Therefore, the minimum time required to image the entire mouse in 3D is $15 \times 15 \times 15 \times 0.01 \text{ s}$, or approximately 30 s . Since 900 s (15 min) still meet safety standards, 30 averages per point can be safely acquired to lower the detection threshold to $\sim 3 \text{ ng}$ (i.e., $20/\sqrt{30} \text{ ng}$) of magnetite in the allotted imaging time. With 30 averages taking 0.3 s to acquire, $15 \times 0.3 \text{ s}$ is required to translate the mouse over its 9 cm length if resolution along the z -axis is 6 mm . This corresponds to a translation velocity of 2 cm s^{-1} , which is typical for commercial, computerized translation stages. Full computer control and automated image acquisition is therefore feasible.

Under the specified conditions the detection limit will be $\sim 3 \text{ ng}$ of magnetite for each resolved volume element. Since 3 ng of magnetite (Fe_3O_4) corresponds with 2.2 ng of iron (Fe), and this represents 38.9 pmol , the minimum detectable concentration is $38.9 \times 10^{-12} \text{ mol}$ per $0.2 \times 0.2 \times 0.6 \text{ cm}^3$. This is just $1.6 \times 10^{-9} \text{ mol cm}^{-3}$ or approximately $1.6 \mu\text{mol l}^{-1}$. To further qualify this concentration, consider that an FDA-approved dose for iron oxide contrast agents is $15 \mu\text{mol Fe}$ per kilogram tissue. Since the average adult mouse has a total blood volume of 79 ml kg^{-1} , the injected iron concentration in circulating blood at the approved dose is initially expected to be just below $200 \mu\text{mol l}^{-1}$. Given that a minimum SNR of 5 corresponds with $1.6 \mu\text{mol l}^{-1}$, a value of 625 would be achieved after initial injection. If one wished to monitor nanoparticle kinetics in blood, two-dimensional images over a square field of view 3 cm on a side could be collected every minute. Alternatively, if a 2D image was first used to identify major blood vessels, and then the mouse was translated under computer control to center a blood vessel on the system's gradient origin, nanoparticle kinetics in blood could be followed with 300 ms temporal resolution. If sampling once a minute sufficed, additional signal averaging would drop the detection limit to $\sim 113 \text{ nmol l}^{-1}$. The combination of 2D imaging, volume selection, and then focused signal measurements on a region of interest

therefore serves as a powerful analytical platform for measuring nanoparticle kinetics in blood or organs. Conceptually, this technique is similar to localized spectroscopy that is used to measure metabolic profiles with MRI.

Scalability, Deconvolution, and Future Prospects

The imaging example described here highlights MPI's potential as a quantitative dosimetry platform suitable for preclinical research with small rodents. Scalability for human imaging is, however, less clear. Although MPI's inventors have projected performance for a human scanner that is large enough for brain imaging, simulations ignore nanoparticle relaxation and consider core sizes that exceed known thresholds for superparamagnetic behavior. Their projections therefore overestimate possible sensitivity and resolution. Of course, the true test will be real experiments, and given MPI's potential, these will undoubtedly be done.

In previous MPI experiments, resolution was significantly improved by using image deconvolution. In optical microscopy, this has been shown to improve PSF-limited resolution by at least a factor of 4. Consequently, resolution of $\sim 500 \times 500 \times 1500 \mu\text{m}^3$ is possible if the magnet assembly shown in **Figure 9** is ultimately used in conjunction with deconvolution for visualizing magnetic nanoparticles in live mice. At such resolution, the minimum detectable iron concentration would be 64 times higher ($\sim 102 \mu\text{mol l}^{-1}$), which is still realistic for biomedical applications. Conversely, resolution could be

maintained at $2 \times 2 \times 6 \text{ mm}^3$ and deconvolution could be exploited for reducing gradient requirements by a factor of 4 along each axis to facilitate gradient generation and imaging over larger sample volumes.

Of course, MPI's real attraction is the linear relationship between signal strength and nanoparticle amounts. In applications ranging from targeted drug delivery and toxicology, this provides a quantitative platform for non-invasive nanoparticle dosimetry. Given MPI's inherent flexibility, there is little doubt that this attractive attribute will be widely used, particularly since compromises between resolution and sensitivity make it possible to achieve detection thresholds that suit a broad range of possible biomedical problems.

Introduction

NMR dates from 1938 when Rabi and co-workers first observed the phenomenon in molecular beams. This was followed in 1946 by the NMR work in the laboratories of Bloch and Purcell on condensed-phase samples. In the intervening years there has been a wonderful revelation of how rich this spectroscopy can be, and only a flavour can be given here of the many significant developments. A very detailed account of the history is given in Volume 1 of the *Encyclopaedia of NMR*, which also includes biographies of many of those who created the subject as it is today. A shorter, but still very detailed, history can be found in five articles published in *Progress in NMR Spectroscopy*. Here we present a summary of the main developments under five headings: Establishing the principles; Solid-state and liquid crystal NMR; Liquid-state NMR; Biological applications of NMR; Magnetic resonance imaging. We also present three tables that give some of the important milestones in the development of NMR.

Establishing the Principles

NMR arises because some nuclei may have an intrinsic spin angular momentum, which has the consequence that they also have a magnetic dipole moment. The existence of a magnetic dipole moment for hydrogen nuclei was established in 1933 by Gerlach and Stern, who observed the effect of an applied magnetic field gradient on a beam of hydrogen molecules. The trajectories of the molecules are changed if their nuclei have magnetic moments. Inducing transitions between nuclear spin states by the application of electromagnetic radiation at the appropriate resonance frequency was introduced by Rabi and co-workers, also using molecular beams. In this experiment the beam passed first through a field gradient, which deflected the atoms in a direction dependent on

the value of m , the magnetic quantum number, then through a homogeneous field, where they were subjected to the electromagnetic radiation, and finally through another field gradient whose sign was opposite to that in the first region. If the nuclei in the atoms do not absorb the radiation, then the effect of the two field gradients cancels, and the beam is undeflected. Absorption or emission of radiation leads to a net deflection of the beam. This simple experiment therefore provided a foretaste of the use of gradients to create or destroy signals.

The first successful NMR experiments on condensed-phase samples were done in 1945, and published in 1946, separately by the group at Stanford led by Bloch, who observed the protons in water, and a group at Harvard led by Purcell, who also observed protons, but in solid paraffin. Unlike the beam experiments, in these the detection was of a net nuclear magnetization arising from the imbalance between states with different values of m , and it was crucial for their success that nuclear spin relaxation was occurring at a favourable rate. The first systematic experimental measurements of spin–lattice and spin–spin relaxation rates were published in 1948 by Bloembergen, Purcell and Pound, who also gave an interpretation of their magnitudes in terms of the dynamics of the molecules containing the nuclei.

The magnetic shielding of a nucleus from the applied field by the surrounding electrons was recognized to occur in atoms by Lamb, who published a method for calculating the effect in 1941. The aim of these calculations was to correct for the effect of the shielding on the resonance frequencies observed in molecular beam experiments and hence to obtain the true nuclear magnetic moment. Ramsey extended these calculations to nuclei in molecules in 1949–52, and in this same period the phenomenon was observed in the NMR of condensed-phase samples, first in the resonances of metals and metal salts by Knight in 1949, and in the following year by Proctor and Yu, who observed different resonances for ^{14}N in ammonium nitrate, and by Dickinson, who reported the same phenomenon for ^{19}F in various compounds (e.g. BeF_2 , HF , BF_3 , KF , NaF , CF_3CCl_3). The physicists working on these problems thought these ‘chemical shift’ effects uninteresting and a nuisance, since they impeded the important task of measuring nuclear

gyromagnetic ratios accurately! We can now pinpoint the years 1949–50 as the period when NMR ceased to be predominantly a technique of the ‘physicists’ and when the ‘chemists’ began to realize the potential usefulness of the ‘chemical shift’.

It was also at this time that the effects produced by spin–spin coupling were first observed. Experimental results now preceded theory. Proctor and Yu observed a multiplet for the ^{121}Sb resonance in a solution containing the ion SbF_6^- . They observed only five lines of the seven-line multiplet, and so were sidetracked into attempting to explain the splitting as incomplete averaging of the internuclear dipolar coupling. Dipolar coupling had been observed in molecular beam experiments, and its origin was well understood. The problem facing Proctor and Yu was that this interaction, being entirely anisotropic, should vanish if the molecules are rotating rapidly and isotropically, as in an isotropic liquid sample. Gutowsky and McCall also observed spin–spin splittings, but this time in the ^{31}P and ^{19}F resonances in the compounds POCl_2F , POClF_2 and CH_3OPF_3 . They were able to

deduce that the number of lines is determined by the product of the m values of the coupled nuclei. Ramsey and Purcell published an explanation of the splitting as arising from a rotationally invariant interaction between nuclear spins that proceeds via the electrons in the molecule. Spin–spin splitting was also observed at the same time by Hahn and Maxwell as a modulation on a spin-echo signal, Hahn having discovered the spin-echo phenomenon in 1949.

By 1952 all the basic, important interactions that affect NMR spectra had been demonstrated, and their relationship with molecular structure had been explained (see Table 1). The challenge then, as now, was how to exploit the value of NMR for samples of varying degrees of complexity, and this proved to be an exciting and rewarding quest. There were still many new effects to be discovered, and these began to appear quickly as the early pioneers started to explore this new spectroscopy. In 1953 Overhauser predicted that it should be possible to transfer spin polarization from electrons to nuclei. He delivered this prediction to an initially sceptical

audience at a meeting of the American Physical Society in Washington, DC. Overhauser was a postdoctoral worker in Illinois when he made this prediction, and he had interested Slichter in the possibility of enhancing NMR signals in this way. Slichter and Carver succeeded in demonstrating the enhancement in lithium metal and all doubts about the nuclear Overhauser effect (NOE) were put to rest.

The chemical shift and spin–spin coupling phenomena were clearly destined to be discovered as soon as magnets became sufficiently homogeneous. They might be classed as inevitable discoveries. The Overhauser effect is different, and it is conceivable that it would have lain undiscovered for many years without the perception of one individual. We might call this a noninevitable discovery. One of the remarkable features of NMR development has been the number of such noninevitable discoveries, some of which have been fully exploited only many years after their discovery. Another such example is the invention by Redfield in 1955 of spin locking, a technique that produces a retardation of spin–spin relaxation in the presence of a radiofrequency field. This not only led to a method of studying slow molecular motions, but also provided a method for transferring polarization between two nuclei that are simultaneously spin-locked, as ingeniously demonstrated by Hahn and Hartmann in 1962.

There were many developments going on in the period 1955–65, some of which we will discuss later. The successes of the early pioneers encouraged the development of commercial spectrometers, and this provided increased access to NMR for a wider scientific community. The first commercial spectrometer (30 MHz for ^1H) was marketed by Varian Associates in 1952, and many of the new early developments stemmed from Varian's research and development department. Sample spinning and field-frequency locking are just two examples that led to dramatic improvements in the quality of high-resolution spectra of liquids. However, the most significant development was the pulse Fourier transform (FT) method of acquiring spectra, which Anderson and Ernst realized at Varian, the first account of which appeared in 1966. At that time their spectrometer did not have an on-line, or even a close at hand, computer on which to do the transform, and the exploitation of the method in a commercial spectrometer had to wait for the development of the on-line computer. In fact, the first commercial pulse FT spectrometer was marketed by Bruker in 1969.

Varian introduced superconducting magnets into NMR with a 200 MHz proton spectrometer, first produced in 1962, and whose field strength was soon increased so as to give proton resonance at 220 MHz.

By 1971 NMR was beginning to look like a mature spectroscopy with all the major developments in place.

However, in that year Jeener suggested the idea of multidimensional spectroscopy, and in 1973 Lauterbur published his method for imaging of objects by applying magnetic field gradients. These two events stimulated Ernst and his collaborators to develop the first two-dimensional (2D) experiments, and a new age of rapid development in NMR began, leading to the marvellous portfolio of experiments in NMR spectroscopy and imaging that are available today.

Solid-State and Liquid Crystalline Samples

The rapid and isotropic motion in normal liquids averages the anisotropic interactions to zero. The rapid motion also produces a long spin–spin relaxation time (T_2), and hence a very narrow NMR line. In most solids there is little or no motion and the NMR lines may be split by very large anisotropic interactions, and will usually have a very short T_2 , and hence broad lines. In fact, in the early days of NMR, studies of solids and liquids were seen to be quite different activities. Commercial spectrometers were produced mainly for liquid-state studies, since it was appreciated that the applications of NMR for mixture analysis and structure determination by chemists would be the major market. Spectrometers were usually designed either to obtain high-resolution spectra – that is, to resolve the small chemical shifts and spin–spin couplings exhibited by liquids – or for solid samples, where magnet homogeneity was not so important but special techniques were necessary in order to record the very broad line spectra. The NMR community was divided mainly into those working with liquids and those looking at solids.

We will restrict our description of the historical development of the NMR of solids and liquid crystals to showing how the gap between these two communities has narrowed, and indeed now overlaps. The first steps along this path were taken by Andrew, Bradbury and Eades in 1958, and by Lowe in 1959, who showed that rotation of a solid sample about an angle of 54.7° to the magnetic field can remove the second-rank, anisotropic contributions to NMR interactions for spin- $\frac{1}{2}$ nuclei. This means that, in principle, the dipolar interaction, which is entirely a second-rank, anisotropic interaction, and the anisotropic contribution to the chemical shift can be removed by using this 'magic angle' spinning (MAS) technique. The spectra obtained show spinning sidebands at the frequency of the rotation speed, and have intensities that depend on the relative magnitudes of the rotation speed and the magnitude of the interaction being averaged. The early experiments demonstrated that the spectral lines can be narrowed to reveal chemical shift differences, and even in some cases spin–spin couplings, but the samples

that could be studied in this way were limited, and the method did not find wide application. The MAS experiment had to wait until 1976 before it was used to provide high-quality, high-resolution ^{13}C spectra from solid samples. Carbon-13 is a special case in being isotopically dilute at natural abundance and so the spectra can easily be simplified by proton decoupling. This produces spectra from a liquid sample that have a single line for each chemically equivalent group of carbons. The low isotopic abundance, however, also leads to a low signal-to-noise ratio, and in liquids it was not until the advent of the pulse FT method that ^{13}C spectra with a good signal-to-noise ratios could be obtained by time averaging. For a solid sample the time averaging is often inefficient because the ratio of the relaxation times T_1/T_2 is high. To overcome this problem, Schaefer and Stejskal used an idea proposed and demonstrated by Hahn and Hartmann in 1962 in which the ^{13}C and ^1H nuclei can be made to transfer polarization by subjecting each of them simultaneously to spin-locking radiofrequency fields.

In liquid crystalline samples the molecules move rapidly, so that the NMR interactions are averaged, but they do not move randomly, and this results in nonzero averaging of the dipolar couplings, the chemical shift anisotropies and the quadrupolar interactions. The first reported observation of a spectrum from a liquid crystalline sample was by Spence, Moses and Jain in 1953. It was the proton spectrum of a nematic sample, and consisted of a very broad triplet structure and had a low information content. Ten years later, Englert and Saupe recorded the ^1H spectrum of benzene dissolved in a nematic solvent and this consisted of a large number of sharp lines; its analysis gave three partially averaged dipolar couplings whose values could be related to the relative positions of the protons and the orientational order of the sixfold symmetry axis of the benzene molecule. The study of liquid crystals themselves received a boost with the publication in 1965 by Rowell, Melby, Panar and Phillips of the spectrum given by the deuterons in a specifically deuterated nematogen. They obtained partially averaged quadrupolar splittings, which can be used to characterize the orientational order of the deuterated molecular fragments. The realization that NMR could give useful information about membranes and model membranes dates from the late 1960s and early 1970s, and the particularly valuable role of deuterium NMR in membrane studies stems from the publication in 1971 of a study by Oldfield, Chapman and Derbyshire.

Liquid-State NMR

Following the detection of the NMR phenomenon and the subsequent discovery of the chemical shift and

spin-spin coupling, NMR emerged as one of the most powerful physical techniques for determining molecular structures in solution and for analysing complex mixtures of molecules. The potential of the method as a structural tool was almost immediately recognized. High-resolution NMR spectrometers were constructed in several laboratories (such as those of HS Gutowsky, RE Richards and JD Roberts, and JN Shoolery at Varian Associates) and the pioneering efforts of these scientists and others began to demonstrate the scope of applications of the technique in chemistry. The success of the method for chemists derives from the well-defined correlations between molecular structure and the measured chemical shifts and spin coupling constants. In retrospect, the achievements of the early workers were truly remarkable considering that they were working at such low magnetic fields (30/40 MHz for ^1H) so that spectral dispersion was poor and the sensitivity was at least three orders of magnitude less than in present-day instruments. The ingenious adaptations of their instruments to increase the stability and resolution (for example, field-frequency locking, homogeneity shim coils and sample spinning) were absolutely essential to allow them to make progress in their structural determinations. As time progressed, the sensitivity was boosted initially by increasing the field strengths and improving the radiofrequency (RF) circuitry and probe designs, and subsequently by using spectral accumulation and FT methods.

Most of the important milestones in the development of the NMR technique for studies of solution state NMR are given in Table 2. By 1957 NMR was emerging as a powerful nondestructive analytical technique capable of providing structural information about the environment of more than 100 known nuclear isotopes. Initially the technique was held back by its relatively low sensitivity and the complexity of the ^1H spectra of larger molecules. In the late 1950s, although many problems were identified for NMR study in areas such as polymer chemistry, organometallic chemistry and even biochemistry, the method was proving to be grossly inadequate for tackling them. For example, polymer scientists acquired some of the early instruments hoping to determine stereotacticities and cross-linking in synthetic polymers; in fact it was not until several years later that improved instrumentation allowed such problems to be tackled successfully. Meanwhile, the method was enjoying considerable success in helping to solve molecular structures of moderately sized molecules ($M_r < 400$): it was particularly useful in natural product chemistry where it became possible to differentiate between several structures that satisfied the compositional data. It was also proving to be a very powerful method for defining stereochemical details of various structures, for example alkaloids and steroids. Not surprisingly, organic chemists were immediately attracted to this technique, which

could reveal unresolved structural details about some of the molecules they had been studying for decades.

More challenging applications to larger molecules became possible only with the eventual improvements in sensitivity and spectral simplification. Although the manufacturers made steady progress in providing higher and higher field strengths, it was not until 1966 that a significant impact was made on the sensitivity problem with the arrival of FT methods and the use of dedicated computers for data acquisition. These methods also facilitated studies of less-sensitive nuclei and from 1966 to 1975 ^{13}C studies at natural abundance became routine not only for structural studies but also for investigating rapid molecular motions (obtaining correlation times from ^{13}C relaxation studies). During this period, structural determinations of fairly large molecules ($M_r \sim 3500$) became commonplace and measurements of nuclear Overhauser effects were frequently used to identify protons that were near to each other. Fortunately, while this rapid expansion in applications work was underway, a few research groups continued to concentrate on understanding the basic spin physics. Some of the novel multipulse techniques developed at this time (such as INEPT and HMQC for indirect detection of insensitive heteronuclei via proton signals) were to prove of far-reaching value in eventually simplifying complex NMR spectra from large macromolecules.

Biological Applications of NMR

Biochemists became interested in the NMR technique long before it could provide them with the detailed information they were seeking. For example, the first ^1H spectrum of a protein was recorded in 1957 and proved to be almost featureless. From these unpromising beginnings, who would have predicted that later the technique would be used to fully assign the resonances of proteins and to determine their three-dimensional structures? Early workers such as M Cohn, O Jardetzky and RG Shulman had sufficient vision to recognize the eventual potential of the method when they began their pioneering studies on nucleotides, amino acids, peptides, proteins, paramagnetic ion effects and metabolic applications. In the early days, brave attempts were made to solve the problem of signal overlap by studying partially deuterated, large biological macromolecules at ever-increasing field strengths. However, a general solution to the signal overlap problem became available only with the arrival of multidimensional NMR methods.

The most important breakthrough came in 1975 with the development of the first 2D NMR experiments, which had the capability of both simplifying complex spectra and also establishing correlations between nuclei connected either by scalar spin coupling through covalent bonds (COSY spectra) or by dipole–dipole

relaxation pathways through space (NOESY spectra). These 2D experiments allowed the assignment of complex NMR spectra and provided distance information for use in structural calculations. The eventual demonstration of the full potential of these methods was made by Wüthrich and co-workers, which eventually led to the first determination of a complete structure for a globular protein in solution.

The extension of the multidimensional NMR approach to larger proteins was subsequently made possible by the development of 3D- and 4D-NMR techniques incorporating INEPT and HMQC pulse sequences that were applied to ^{13}C - and ^{15}N -labelled proteins. These latter developments were made at NIH by Bax and Clore and their co-workers. These multidimensional NMR methods provide the spectral simplification required to completely assign the spectra of proteins of up to 30 kDa and to determine their structures to a resolution similar to the 0.20 nm resolution X-ray structure (see the

relevant milestone experiments in Table 2). Using the modern techniques, detailed structural and dynamic information can now be routinely obtained for complexes of proteins formed with nucleic acids and other ligands with overall molecular masses of ~ 30 kDa. More recently the use of novel pulse sequence such as TROSY has enabled the study of much larger proteins.

In the early 1970s a completely new area of NMR was opened by reports (by Moon and Richard and by Hoult and co-workers) showing that it was possible to record high-resolution ^{31}P NMR spectra on cells and intact organs. This led to an exciting area of research into metabolic processes that allows the chemistry within living cells to be monitored directly. These methods have reached the stage where they can be used to diagnose disease, to monitor biochemical responses to exercise and stress, and even to follow the effects of drug therapy by using repeated non-invasive examinations. The possibility of combining this approach with spatial localization

techniques in whole-body magnetic resonance imaging (MRI) presents enormous opportunities for future work.

Magnetic Resonance Imaging (MRI)

Many of us can recall the great intellectual excitement that accompanied the publication of the early NMR experiments in 1973 showing how spatial information can be encoded into NMR signals. In particular, the simple approach adopted by Paul Lauterbur of using field gradients to produce the spatial resolution required to give a 2D image of water in glass tubes was a brilliant example of lateral thinking that provided a completely new way of viewing the NMR experiment. Even in the very early days, the pioneering workers in MRI (the word 'nuclear' having been dropped because it was thought that it would suggest to the patients that radioactivity was involved) realized that the technique would make its largest contribution in the area of noninvasive clinical imaging. By 1977 the first images of the human body were being reported, one of the earliest being that of a wrist showing features as small as 0.5 cm. At first the method was greeted with much scepticism because its sensitivity performance compared unfavourably with the well-established X-ray CT scanning methods: however, rapid instrumental advances soon allowed the MRI technique to show its full potential, particularly in the ability to provide high-contrast images for soft tissues and tissues in areas surrounded by dense bone structures. The development of the echo planar imaging (EPI) method by Mansfield and his co-workers allowed well-resolved images to be obtained from a single pulse sequence and this opened up many new applications requiring short examination times, such as in heart, abdomen and chest imaging. Other important milestones in the development of the MRI technique up to the mid-1990s are summarized in **Table 3**. There are now many applications where MRI is the favoured imaging method (such as brain scanning for detecting encephalitis or multiple sclerosis (MS) and for monitoring therapy treatment

of MS). Most of the images examined are based on detecting ^1H nuclei. However, high-quality images of the airways in human lungs have been provided by helium or xenon images obtained after inhalation of the polarized inert gases by the patient. Another exciting application, called functional MRI, attempts to study the working of the human brain; by stimulating the brain either through the senses or by thought processes, it is possible to detect changes in MRI images of the brain. These are related to changes in oxygen levels in the blood induced in specific locations of the brain. This type of experiment opens up exciting possibilities for studying the human brain in action.

MRI scanners are now used not only in research hospitals but also in the general hospital environment. The high-profile use of MRI as a major health-care tool has certainly increased the public awareness of NMR and drawn proper attention to the versatility of this exceptional phenomenon.

Imaging Mass Spectrometry: An Introduction

Imaging mass spectrometry (IMS) is a very sensitive molecular imaging technique that provides combined molecular information and spatial resolution. It allows the identification and localization of elements and molecules directly from tissue sections, single cells, and many other surfaces. The key features for applied imaging mass spectrometric studies are the sensitivity provided by modern mass spectrometers, the label-free nature of the technique, the ability to image post-translational modifications of peptides and proteins, and the spatial resolution that ranges from the organism (hundreds of micrometers) to the cellular level (tens of nanometers). IMS allows the simultaneous detection of thousands of different molecular images in one single experiment. As such it constitutes an efficient, multi-component molecular imaging technique. Many different IMS protocols and instruments have been developed to study the distribution of endogenous biological

compounds such as lipids, peptides, and proteins, and exogenous compounds such as polymer or drugs designed for tissue treatment. These studies provide a detailed understanding of biological processes from the subcellular to organism level.

Today, IMS is predominantly an *ex vivo* tissue histology technique used in pathology and offers no *in vivo* diagnostic capabilities as MRI (magnetic resonance imaging) or PET (positron emission tomography) scans do. However, it is successfully employed as a complementary technique to *in vivo* imaging to validate the molecular repartition or degradation of biomolecules or drug delivery in various disease stages. Many researchers are pursuing this approach of complementary imaging modalities to address specific questions related to molecular distributions. The rationale of this approach is evident. No single imaging technique is capable of providing the proper combination of molecular and anatomical information at the appropriate spatial resolution, time resolution, and biological state. Compared to other molecular imaging approaches such as MRI, PET, or immunohistochemistry (IHC), IMS offers one unique feature: IMS can visualize molecules without labeling of compounds, which allows the discovery of new compound distributions that no other technique is capable of. Often, it is the only tool that allows the molecular substantiation of aberrations that become visible with conventional staining agents such as hematoxylin and eosin (H&E) commonly used in tissue histology. It can also visualize alterations in molecular distributions that are not visible with conventional histological staining agents. This results from the fact that conventional staining agents used in pathology offer general tissue typing without identifying specific molecules, molecular modifications, and combinations thereof. Several drugs and metabolites will not be stained with the common histological staining agents listed in Table 1.

Desorption and Ionization Techniques for Imaging Mass Spectrometry

IMS requires desorption and ionization of molecules from the surface under investigation. Two physical methods can be distinguished that are employed to establish this: (1) the irradiation of the surface with energetic charged particles and (2) the irradiation of the surface with photons from a pulsed coherent light source.

Table 1 A concise overview of common histological staining agents with their main applications. Imaging MS is added for comparison

<i>Staining agent</i>	<i>Tissue/Organelle type</i>	<i>Molecular class stained/ visualized</i>	<i>Remarks</i>
Hematoxylin	Nucleus	Nucleic acids	Also stains endoplasmatic reticulum. Typically used in combination with eosin
Eosin	Cytoplasm, red blood cells, and collagen fibers	Elastic fibers and reticular fibers	Typically used in combination with hematoxylin
Toluidine blue	Various	Mast cells granules	General purpose staining
Silver stain	Neurons, glial cells, neurofibrils, fungi	Reticular fibers, argyrophilic tissue	Melanin and reticular fibers can be differentiated
Sudan stains	Membranes, atherosclerotic plaques	Lipids, phospholipids	Different stains are Sudan black, Sudan IV, oil red O
Congo red	Amyloid plaques	Amyloid	
Cresyl violet	Neurons, glial cells, ribosomes, nucleus, and nucleoli	Nucleic acids	
Imaging MS	All	Various and differentiated by <i>m/z</i>	No chemical modification of molecular constituents of tissue

Desorption and Ionization with Charged Particles

Charged particles are predominantly employed in imaging with secondary ion mass spectrometry (SIMS). In this approach, the analyte surface is exposed to an energetic, focused primary ion beam. The impinging ions cause a collision cascade on and below the surface that leads to the removal and ionization of surface molecules. The produced secondary ions are subsequently mass analyzed to determine their identity. Typically, the dose is kept low to ensure that each primary ion interacts with a different surface area and that a damaged area is not reanalyzed. Experiments below the dose where only fresh surface areas are sampled are referred to as static SIMS experiments. Above that dose experiments are entitled dynamic SIMS experiments, as the surface will be continuously changing during the experiment. In a static SIMS experiment, typically less than 1% of the surface is analyzed.

During a SIMS experiment, a significant amount of internal energy is imparted into the surface molecules. This results in a significant amount of fragmentation already in or above the surface. This renders the method less suitable to study large molecular species, such as peptides and proteins, directly. It provides a good insight into the elemental and small molecular distribution on surfaces. Fragmentation patterns found are similar to the fragmentation observed in electron impact ionization.

Most commonly used elemental primary ion species are indium and gallium. Their main application is the study of elemental and organic impurities on semiconductor surfaces as well as the study of thin-layer surface coatings. Biological surfaces such as histological tissue sections benefit from the application of larger cluster ions or molecular ions as primary species. Larger

primary ions such as Au_n^+ , Bi_n^{m+} , and C_{60}^+ result in a larger yield of intact secondary molecular ions and reduced fragmentation. In addition, the damage to the underlying layers is significantly reduced, allowing the possibility to perform three-dimensional imaging experiments.

All SIMS experiments, with the primary beams described, are performed under vacuum conditions as the mean free path of the primary ions would be too short to allow them to reach the surface. Desorption electrospray ionization (DESI) is an ambient desorption and ionization technique. It utilizes pneumatically assisted electrosprayed droplets that are directed onto a surface to be analyzed at atmospheric conditions. The solvent droplets 'pick up' surface molecules, generating secondary ions of which the mass spectra resemble common electrospray mass spectra. This means it is possible to generate multiply charged pseudomolecular ions. This method has been shown to be suitable for the analysis of a wide variety of surfaces, including pharmaceutical tablets, bloodstains, and tissue sections. Tissue imaging with DESI has been shown to visualize phospholipids and lipids from the brain and oncological tissue sections.

Desorption and Ionization with Photons

LDI and MALDI

The second method that is capable of desorbing and ionizing molecules from surfaces is based on the interaction of photons with the surface. Typically, a pulsed laser beam is focused on an analyte surface. The absorption of photon energy by the surface layer causes an explosive removal, or ablation, of surface material. The photon energy is mainly imparted into rovibrational surface modes when infrared (IR) or visible light is used. In the UV or vacuum UV (VUV), a significant amount of

electronic excitation results from the increased photon energy. If the amount of internal energy deposited in the removed elements molecules is sufficient to lead to direct ionization, the process is called laser desorption and ionization (LDI), as shown in **Figure 1(a)**. Often the amount of internal energy deposited in the laser desorption process is so high that a significant amount of fragmentation occurs. In addition, the low ionization efficiency for organic compounds makes the technology less suited for macromolecular MS. In selected cases, a laser desorption post-ionization (LDPI) strategy can be applied to ionize the plume of neutrals generated in the desorption process (**Figure 1(b)**). Post-ionization can be established under vacuum conditions by a second energetic laser beam in the UV or even VUV wavelength range. Recent developments have shown that laser desorption can be efficiently coupled to an ESI source, resulting in laser ablation electrospray ionization (LAESI) in an ambient environment under atmospheric pressure conditions (**Figure 1(c)**). This combination extends the class of molecules that can be analyzed with laser desorption strategies and reduces the amount of fragmentation observed. Laser ablation is successfully used for quantitative elemental analysis of surfaces when combined with inductively coupled plasma mass

spectrometry (ICP-MS). The ablated components are atomized and ionized by the plasma source into constituent elemental and isotopic ions that are subsequently analyzed by a mass spectrometer. When combined with optical emission spectrometry, the spectrally resolved light emitted from the ICP is used to provide additional quantitative elemental information.

Owing to the extensive amount of fragmentation, direct LDI strategies are less suited for the analysis of intact biomolecules with a molecular weight that exceeds 500 Da. The use of an energy-moderating matrix in which analytes are mixed in or that is applied on top of a surface to be analyzed (see **Figure 1(d)**) can overcome this limitation. This technique, conceived in the late 1980s by Karas and Hillenkamp, is referred to as matrix-assisted laser desorption and ionization (MALDI). It is a key technology in modern proteomics research and allows desorption and ionization of very large biomolecules such as intact protein and DNA molecules. In MALDI on complex surfaces, the matrix solution serves a number of purposes. First, after application, it extracts the molecules from the complex sample and reconstitutes them in or on top of matrix crystals. The formation of these analyte-doped matrix crystals segregates the analytes from detrimental cofactors such as salts, and

Figure 1 Schematic representations of different desorption and ionization strategies that employ laser beams.

disentangles and isolates the large molecules in a sea of matrix. Subsequent illumination of the crystal surface with the pulsed laser light superheats the sample rapidly. This is a direct result of the fact that the matrix acts as a strong absorber of the laser energy through electronic (UV-MALDI) or vibrational excitation (IR-MALDI). A cooperative motion of the superheated matrix is directed into the vacuum, in which the analyte is entrained. This facilitates a nondestructive transition of the analyte molecules to the gas phase. The last purpose of the matrix is the promotion of the ionization of the analyte molecules by charge transfer. This process typically leads to cationized, intact pseudomolecular ions of the type $[M + X]^+$, where X denotes the type of cation produced. Most common cations are hydrogen, sodium, and potassium. For a successful analysis, the analyte molecules have to cocrystallize with the solid matrix material, which should be present in surplus. Matrix-to-analyte ratios that are used most often are in the range of 10^3 to 10^5 :1. As a rule of thumb, one can say that the higher the mass of the analyte studied, the greater the surplus of matrix molecules needed for intact desorption.

MALDI in the ambient environment

The recent developments in ambient desorption strategies have resulted in a number of strategies where a matrix is also employed. An approach similar to LAESI where a matrix-analyte mixture is left to crystallize on a substrate takes advantage of the fact that more intact species can be removed from the surface. The MALDI ions are deflected with an electric field applied between the MS inlet and the sample surface. The neutrals produced from the MALDI target contain a large number of analyte molecules that are discarded in vacuum MALDI experiments. They are picked up on the surface of electrospray-generated droplets that have not yet been fully dissolved. What follows is a conventional electrospray ionization process that leads to multiply charged analyte ions. This process, acronymed MAL-DESI (matrix-assisted laser desorption electrospray ionization), combines the benefits of MALDI in the ambient environment with the sensitive detection of multiply charged electrospray-generated ions.

MALDI and liquid chromatography

MALDI has been successfully coupled to liquid chromatography (LC) separation technology to improve the detection efficiency in complex mixtures. MALDI suffers from significant ion suppression when complex mixtures are analyzed. The presence of many different analyte molecules with many different physicochemical properties often results in the preferential ionization of one component over the other. The ion suppression effect is a major obstacle to quantification in many analytical disciplines. The interpretation of intensity differences in

MALDI mass spectra is intrinsically qualitative. One way to overcome this issue is by performing chromatographic separation to reduce the complexity of the mixture. A number of nano-LC-MALDI approaches have been implemented that convert the separation timescale into a spatial distribution. Robotic spotting technology is used to deposit an array of nano-LC eluent droplets, typically 150 nl per droplet, onto a precoated MALDI target. Other approaches mix a matrix solution with the LC eluent and deposit a droplet array of this mixture onto a clean target plate for a mass spectrometer.

Matrix Usage in SIMS

The advantages of the use of an energy-moderating matrix material are not exclusively limited to photon-based desorption and ionization technologies. The success of MALDI has initiated the use of MALDI matrixes in SIMS sample preparation. Cocrystallization of analytes with MALDI matrixes such as 2,5-dihydroxybenzoic acid (DHB) facilitates the detection of macromolecular ions of masses over 10 kDa in a methodology termed matrix-enhanced SIMS (ME-SIMS). Thereby, it is, at present, the only SIMS-based ionization methodology that is successful in the generation of intact high-mass biomolecular (peptides, proteins, oligonucleotides) ions. It was suggested that the role of the matrix in ME-SIMS bears similarities to that in MALDI: providing a nestle environment for the analyte molecules and a source of protons to enhance ionization. Best results were obtained with DHB as matrix; as a possible explanation for this, it was argued that DHB would promote the concentration of analyte species in the surface region of the sample. Since ME-SIMS (as opposed to MALDI) examines the topmost 50 nm of the surface only, the localization of the analyte species is crucial to the sample preparation process. The analyte molecules have to be present at the surface of the crystals as the deeper layers of a matrix crystal will not be accessed under static SIMS conditions.

Spatial Resolution for Imaging MS

One key parameter for IMS is the achievable spatial resolution. The spatial resolution determines what detail can be observed from cellular and tissue surfaces. The most common method of generating mass-resolved images is using the microprobe or scanning mode. Microprobe mode MS imaging is performed by scanning the ionizing probe beam across a sample (SIMS) or by moving the sample through its focus (MALDI). For every position, the ionizing beam interacts with the sample, the coordinates are stored, and a mass spectrum is obtained (position-correlated ion generation). In this way, a raster is built; every point in the raster has a mass spectrum associated to it. Using dedicated software, mass-resolved

ion images can be constructed from such datasets. The maximum achievable spatial resolution in a microprobe imaging experiment is determined by the size of the microprobe. Technically, the accuracy with which each point in the raster is defined is another factor controlling the resolution, but for SIMS and MALDI imaging, generally, this is not an issue. Further, the experimentally achieved spatial resolution is influenced by factors related to sample preparation (application of matrix) and sensitivity (signal-to-noise ratio).

Spatial Resolution in SIMS and DESI

Liquid metal ion guns constitute the majority of primary ion sources used in SIMS. Ga^+ and In^+ are predominantly used in elemental and small molecule analysis of surfaces. The spatial resolution that can be obtained with these guns is determined by the size of the emitter, the electrostatic optics in the ion column, and the primary beam current. The latter is typically kept low to prevent space charge expansion of the beam and loss of resolution. These two guns can provide a focus of 50 nm when well tuned at low currents. The metal cluster beams Au_n^+ and Bi_n^+ as well as C_{60}^+ can provide a spot size of 100–200 nm at very low beam currents. The low beam currents result in long experimental timescales. As a result spatial resolution is often compromised and reduced to approximately 1 μm to increase the analysis speed through the application of larger primary beam currents. DESI uses a jet of charged solvent droplets directed at the surface. The size of the wetted interaction area with the surface determines the spatial resolution. Typical spatial resolutions for imaging DESI have been reported to be in the order of 1 mm.

Spatial Resolution in LDI and MALDI

The resolution of a focused laser beam is wavelength dependent and governed by the Abbe diffraction limit. A long wavelength IR laser is difficult to focus below 50 μm . The physical size of a UV laser spot in commercial instruments is limited to approximately 10 μm . On commercial instruments, most experiments are performed with a laser spot size between 50 and 250 μm . This choice is determined by sensitivity and the time required to complete an experiment. Special confocal-type objectives can reduce the spot size to 1 μm , but there is substantial debate if the laser threshold fluence required for the use of these small spots with MALDI is not too high for intact molecular analysis directly from tissue. Initial experiments have shown the capability to acquire high-resolution images of smaller species. An alternate approach to increase spatial resolution using conventional MALDI-ToF instruments is the oversampling approach. In this approach, the incremental movement of the laser probe spot is smaller than that of

the spot diameter. After all samples have been consumed at the first spot, each incremental step delivers information from an area much smaller than the size of the laser focus. As a result, the spatial resolution can be increased. The limited tandem MS possibilities and the total sample consumption are two drawbacks of this approach.

Instrumentation for Imaging MS: Developments and Areas of Improvements

Using the desorption and the ionization technologies described in the previous section, it is possible to generate elemental and molecular ions from complex surfaces. The generation of mass spectrometric images with these ions requires subsequent mass analysis. Modern MS offers a wide range of analyzers that can be used for this purpose. This article describes three types of analyzers that offer a unique capability for MALDI or SIMS imaging of biological surfaces.

Time-of-Flight Imaging Mass Spectrometry

The most commonly used mass analyzer in IMS is the ToF analyzer. It requires the pulsed generation of ions. This requirement is ideally compatible with both MALDI and SIMS. All ions experience the same acceleration potential. Ions of equal mass over charge ratio will receive the same kinetic energy on top of their initial kinetic energy, resulting from the desorption process. As a result, their velocity is dependent on their mass over charge ratio, and ions can be separated by allowing them to drift in a field-free region. Ion detection is performed using particle detectors such as multichannel plates (MCP). ToF analysis offers an extremely wide mass range that is only limited by detection sensitivity for large molecular weight species. Analysis up to several megadalton size-species has been performed with MALDI-ToF-MS. The high transmission efficiency and total flight times in the microseconds range offer possibilities of using high-repetition-rate lasers for sensitive surface examination. This enables high-throughput analysis that is a key requirement for the analysis of larger surface areas. Mass resolving power can be improved through the use of techniques that compensate for initial kinetic energy spread, resulting from the desorption process. The use of techniques such as delayed extraction, hemispherical electrostatic sector devices, and reflectrons can increase the full width at half maximum height (FWHM) mass resolving power up to $m/\Delta m = 30\,000$ at $m/z\,1000$. Tandem MS for compound identification is usually performed through collision-induced dissociation (CID) or through the observation of post-ionization metastable decay. For this purpose, two

separate ToF systems are coupled in a so-called ToF/ToF configuration. The first ToF is employed for precursor selection and the second ToF for product ion analysis.

Fourier Transform Ion Cyclotron Resonance Mass Spectrometry

Fourier transform ion cyclotron resonance mass spectrometry (FT-ICR-MS) is a trapped ion technique that determines the cyclotron frequency of ions trapped in a Penning trap inserted in a strong magnetic field. After ion generation in an external ion source, the ions are transferred to the Penning trap where they are stored until further analysis. Using a broadband radiofrequency electrical excitation, all ions are excited to a large cyclotron orbit. Not only is their orbital radius increased, but ions of the same mass over charge ratio also orbit coherently in the Penning trap. During their orbit, they induce an oscillating image charge in a set of two detection electrodes. This time-domain signal is digitized and Fourier transformed to yield the cyclotron frequency spectrum. Calibration based on the cyclotron equation $\omega = qB/m$ results in the mass spectrum.

The main advantage of FT-ICR-MS is that it has unsurpassed mass resolving power and mass measurement accuracy that can be employed to reveal new spatial detail from MALDI image analysis. In addition, the use of trapped ion technology allows not only CID but also infrared multiphoton dissociation (IRMPD) and electron capture dissociation to be used for structural determination using tandem MS. Analysis speed is limited by the length of the observed time-domain signal and the associated mass resolving power. The mass resolving power is dependent on the coherence time of the orbiting ions. A typical analysis time is 1 s per pixel independent of the ion source used. The transient length at the same resolution can be reduced by increasing the magnetic field strength. MALDI tissue imaging experiments have been performed on FT-ICR-MS systems at FWHM-resolution ranging from 40 000 to 400 000. (Figure 2).

MALDI Ion Mobility Imaging Mass Spectrometry

Additional information can be generated from MALDI-generated ions through ion mobility separation. Ion mobility spectrometry is a separation technique based on the collisional cross-section of an ion. In ion mobility MS, a gas-filled drift cell is used to separate ions that have different collisional cross-sections due to either conformational or compositional changes before their mass spectrometric analysis. A gas-phase separation dimension, the drift time, is added in addition to two spatial dimensions and a mass spectral dimension when applied to mass spectral imaging. Ion mobility spectrometry benefits MALDI imaging MS in two major

Figure 2 MALDI Fourier transform ion cyclotron resonance imaging of the left side of a coronal rat brain section. The three images shown correspond from left to right to the spatial distributions of mass spectral peaks found at m/z 1293.68 (left image), m/z 1293.75 (middle image), and m/z 1293.91 (right image) and demonstrates how increased resolution is employed to reveal new features.

ways. First, the addition of an additional separation dimension enables the detection of more MS peaks. Ion mobility decongests the mass spectrum and allows the separation of chemical classes, for example, peptides and phospholipids. Second, the combination of mass with drift time selection criteria enables the differentiation of isobaric peptides or other nominal isobaric species contributions to a fragmentation spectrum.

The combination of ion mobility and MALDI with a ToF-MS for IMS enables localization and identification of proteins via their related digested peptide fragmentations. Ion mobility separates isobaric ions that cannot be identified by conventional MALDI-ToF-MS. The amount of observed peaks per measurement increases (versus conventional MALDI-ToF), which enables the generation of mass and time selected ion images and the identification of separated ions. The results shown in Figure 3 demonstrate the feasibility of direct protein identification by ion mobility-ToF-IMS (IM-ToF-IMS)

Figure 3 On-tissue identification and repartition of two nominally isobaric tryptic peptides at m/z 1039 coming from an enzymatic digestion of an FFPE rat brain analyzed with MALDI ion mobility MS imaging. Used with permission from Heeren RMA, Smith DF, Stauber J, Kükrer-Kaletas B, and MacAleese L (2009) Imaging mass spectrometry: Hype or hope. *Journal of the American Society for Mass Spectrometry* 20: 1006–1014.

from tissue. The tissue digestion combined with MALDI-IM-ToF-IMS approach allows a proteomics ‘bottom-up’ strategy with different kinds of tissue samples.

MALDI Imaging Strategy

Imaging MS Workflow

The different desorption and ionization approaches combined with the different mass analyzers provide the possibility to perform complementary experiments on a single tissue sample. A careful experimental design is required to ensure that relevant complementary molecular image information is obtained. The experimental workflow displayed in **Figure 4** provides an example of the generation of six complementary image datasets from a single tissue. In this example, a piece of tissue is surgically removed. Cells in the tissue express a fluorescently labeled protein, so the step in the imaging workflow is the generation of a fluorescent image. This provides the detailed location of one specific protein. After subsequent tissue sectioning and mounting of the 10–20 μm thin section on a substrate surface, a SIMS analysis is performed. This provides low molecular weight imaging MS data at high spatial resolution. Static SIMS removes less than 1% of the surface material so the residual surface is still amenable to further analysis. After the SIMS study is complete, the tissue surface can be covered with a matrix coating (see the section ‘Matrix coating’). Depending on the analyte of interest, the surface can or cannot be washed. The washing protocol has a significant influence on the results obtained. In the experimental workflow in **Figure 4**, no washing was applied before matrix deposition to allow imaging of small, water-soluble molecules. After matrix deposition, the first analysis performed is ME-SIMS. Again only few molecules are removed from the surface and the crystal

surface remain available for later MALDI analysis. The ME-SIMS dataset provides information on larger intact organic molecules such as lipids and small signaling molecules with a molecular weight < 2000 Da. The next analysis performed is MALDI-ToF analysis with a laser fluence slightly above desorption threshold. The MALDI-ToF dataset contains information on endogenous peptides and intact proteins (depending on the washing protocol and matrix used). The last MS imaging dataset that can be obtained is an MALDI-FT-ICR-MS dataset (or a ion mobility image dataset). These techniques require the removal of most matrix material. They provide high-mass resolution and mass accuracy information that aids in the identification of the molecules that constitute the images. Any residual matrix material can be washed off the heavily analyzed surface to allow a final H&E stain to be carried out. This gives additional histological information that can be used to identify specific areas and/or tissue types in combination with the imaging MS datasets.

Matrix Coating

The matrix solution must be applied on the surface of the tissue before MALDI and ME-SIMS analysis. The matrix solution consists of an organic solvent like methanol or acetonitrile, weak organic acids like sinapinic acid (SA) or 2,5-dihydroxybenzoic acid (DHB) and trifluoroacetic acid (TFA) as an additive. The addition of TFA increases the amount of protons that will enhance the ionization of molecules. The matrix application method will strongly influence the imaging MS results. The application method will have effects on sensitivity, diffusion combined with loss of spatial integrity, spatial resolution, surface flatness, and analysis speed. Tissue properties and environmental parameters affect the extraction efficiency of proteins from tissue and

Figure 4 Multimodal complementary molecular imaging workflow. The same tissue sample is analyzed successively by SIMS, ME-SIMS, MALDI-ToF-MS, and MALDI-FT-ICR-MS after fluorescence images have been obtained.

the crystallization of the matrix. As a result, it is also important to control the matrix deposition environment. Innovative deposition methods such as matrix sublimation are under consideration by a few laboratories. Two general matrix deposition methods can be discerned for general laboratory usage: spotting and spraying.

Matrix spotting

The spotting of the matrix solution onto the tissue section limits diffusion of the analytes to the spot size. Two methods of matrix spotting have been developed: manual or automated spotting. The manual spotting creates microliter droplets and is often used for tissue profiling with MALDI where no image needs to be generated. Robotic spotting utilizes much smaller volume (pL) droplets and results in a spot size of approximately 120–150 μm and minimum resolution of approximately 200 μm . Two different types of robotic spotters are employed for matrix deposition: inkjet-style piezo nozzles and droplet dispensers that employ focused acoustic waves. Both ejectors can release 100 pL drops that dry on the tissue into a 150 μm diameter spot. The resolution of imaging MS analysis is limited in this case by the matrix spot that is generally larger than the diameter of the analytical beam.

Matrix spraying

Matrix spraying coating covers the whole surface of the sample with an even layer of small droplets of matrix solution. Pneumatic or vibrational spray heads and

electrospray are used to generate a nebula of droplets from a matrix solution. The spraying can be carried out in a manual and automated manner. Manual spray coating employs a handheld pneumatic airbrush or TLC sprayer. Automated spray application is realized through the coupling of a spray device to an x-y robot allowing matrix deposition over larger areas. Automatic spraying is also realized for smaller areas using a vibrational sprayer in a small chamber of which the humidity is actively controlled. Crystals formed after spray coating are typically in the order of 10–20 μm . To achieve smaller crystals, electrospray deposition can be used to generate crystals even smaller than 1 μm at the expense of sensitivity. The diameter of the laser beam limits the spatial resolution for MALDI imaging MS when spray deposition is used.

Identification Strategies

The identification of mass spectral peaks used to generate molecular images is a crucial step in all mass spectral imaging strategies. In selected cases, high-mass resolution in combination with accurate mass measurements can be used. Often additional strategies such as tissue MALDI tandem MS or other analytical strategies are required to identify the surface species.

MALDI tandem mass spectrometry

The use of tandem MS is a logical choice to identify different ions generated at the surface. Limiting factors

are the resolution of precursor ions selection, fragmentation efficiency, and sensitivity of the approach. On the same position, often only a few MS experiments can be carried out. The number of experiments that can be carried out on a single position depends on the number of laser shots that still provides signal. Interlaced imaging approaches where the tandem MS experiment is performed at an adjacent location can be used to partially overcome this problem. Multiple reaction monitoring can be applied to determine compound distributions once the fragmentation pattern is known.

LC-MS/MS for Identification

Complementary tissue homogenization and extraction can be used to generate libraries of tissue components. LC-MALDI can be employed to resolve the complexity of the mixture and increase the sensitivity and reduce ion suppression effects. Comparative analysis of the MALDI atlas with the peaks observed in the direct MALDI imaging experiment can be used as part of the identification strategy. In these studies, tandem MS can be used to identify the individual components found on the LC-MALDI target.

Introduction

Mass spectrometry (MS) has made many notable contributions to chemistry from the chemical physics of small molecules to the structures of large biomolecules. It is an instrument in which ions in a beam are separated according to their mass/charge ratio (m/z). Its humble beginnings lay in the works of physicists at the turn of the 19th and 20th centuries. Up to the Second World War, MS was the province of physicists along with a small band of physical chemists. However, the demands for accurate evaluation of the composition of aircraft fuel during the Second World War led to its extensive application to hydrocarbon analysis. Heartened by the success in this area, operators were encouraged to put 'dirty' organic chemicals in their instruments and so organic MS was born. These developments were largely due to the manufacturers responding to the demands for instruments to meet the needs of the chemists. The introduction of high-resolution instruments led to the developments of ion chemistry. This took place in the decades 1950–1980. By this time, the mass spectrometric study of large organic molecules had been achieved and the prevailing interest switched to biomolecules – a good source of financial support in view of their medical relevance.

One of the important aspects of the development of MS was the camaraderie (occasionally blighted by periods of frustration) that existed between the users and the manufacturers. This was nurtured by the introduction of user's meetings by Associated Electrical Industries (an offshoot of Metrovick). The users would foregather with the engineers responsible for instrumental development to explain *their* problems and requirements for instrument development. The author remembers well the confidence he gained from learning that his problems

were not unique – other users had them too! Instrumental development was stimulated by the demands of the users and if the suggested instrumentation could be satisfactorily produced it soon became available. This made it an exciting period to live through. This perspective covers developments up to approximately the mid-1990's.

The Beginnings

Thomson

The origins of MS lie in the work done in the Cavendish Laboratory in Cambridge by JJ Thomson and his colleagues at the start of the twentieth century on electrical discharges in gases. The first relevant work was the discovery of the electron, using a cathode ray tube. The rays from the cathode pass through a slit in the anode (Figure 1) and after passing through another slit pass between two metal plates and on to the wall of the tube. This wall had been treated with a phosphorescent material which glows where the beam strikes it. The beam can be diverted by applying a potential difference between the plates and also by superimposing a magnetic field. By adjusting the two fields so that there is no displacement of the beam Thomson was able to show that the particles carried a negative charge of approximately $10^{11} \text{ C kg}^{-1}$. Goldstein in 1886, using a perforated cathode, was able to show that there was always a beam travelling in the opposite direction to that of the electrons – the so-called kanalstrahlen. Later, Wien showed that these were positively charged particles and concluded that they were positive ions. Thomson decided to investigate these particles. His positive ray apparatus (1912) is shown in Figure 1. A is a discharge tube

Figure 1 Thomson's cathode ray tube.

Figure 2 The parabola.

producing positive ions which then pass through the cathode B and after collimation in the narrow tube BN are subjected to superimposed electric and magnetic fields (M, M', P, P'). The displaced beams then travel to the fluorescent screen G where their effect is observed.

In **Figure 2**, the parabola formed by the top and bottom branches on the left-hand side are due to neon. Under better resolution, they show the presence of isotopes at masses 20 and 22. Isotopes had previously been observed in studies of radioactivity. Thomson encouraged a research student in the Cavendish Laboratory, FW Aston, to build a mass spectrograph for further studies of stable isotopes. The research was interrupted by the war of 1914–1918 and so the work was not published until 1923.

Aston

His spectrograph is shown diagrammatically in **Figure 3**. A beam of ions passes through the collimating slits S_1, S_2 into an electric field P_1, P_2 . It then enters a magnetic field centred on M and the divergent beam is brought to focus on a photographic plate P. The geometry ensures that, irrespective of the velocity of the ions, they are brought to a sharp focus on the photographic plate. This is known as velocity focusing. By 1923, Aston had realized that deviations from integral values of the relative molecular masses (Prout's Rule) were of considerable importance for the study of nuclear structure. However, as will be seen later, they were of inestimable importance in the development of organic MS. Current values for some atoms are shown in **Table 1** ($^{12}\text{C} = 12.000\,000$).

Dempster

In 1918, a Canadian working in the University of Chicago (AJ Dempster) developed a different type of apparatus

Figure 3 Aston's mass spectrograph.

Table 1 Accurate masses of some common atoms

Atom	Relative atomic mass
Hydrogen	1.007 825
Carbon	12.000 000
Nitrogen	14.003 074
Oxygen	15.994 915
Fluorine	18.888 405
Sulphur	31.972 074

Figure 4 Dempster's mass spectrometer.

for investigating positive rays (**Figure 4**). It involved a 180° magnetic field. Ions produced by the filament in G are accelerated into the magnetic field through S_1 and pass through S_2 and hence to the collector E. Such a geometry gives rise to direction focusing – ions will arrive at the collector irrespective of the direction they enter the magnetic field. The experimental arrangement is described by the fundamental equation of sector MS (eqn [1]), namely

$$m/z = 2V/B^2R^2 \quad [1]$$

where m is the mass of the ion, z its charge, B is the magnetic field strength and R is the radius of the magnetic field. A fundamental difference between Aston's instrument and that of Dempster is that Aston's spectra

are obtained instantaneously whereas Dempster's have to be scanned. This can be done simply in two ways, by either scanning the electric field at constant magnetic field or scanning the magnetic field at constant electric field (more sophisticated methods of scanning have been developed, leading to a better understanding of mass spectrometric processes). Most sector mass spectrometers use the latter method.

Instrumental Development

The Basic Mass Spectrometer

In the mass spectrometer shown in **Figure 5**, the sample is held in the reservoir and led into the ionization chamber via a leak. On ionization, the ions are accelerated into the magnetic sector and eventually arrive at the collector. The current is amplified and recorded.

JJ Thomson was very perceptive in predicting organic MS in 1913. He wrote in his book *Rays of Positive Electricity and their Application to Chemical Analysis*. "I have described at some lengths the applications of positive rays to chemical analysis: one of the main reasons for writing this book was the hope that it might induce others and especially chemists, to try this method of analysis. I feel sure that there are many problems in chemistry which could be solved with much greater ease

by this than by any other method. This method is surprisingly sensitive – more so even than that of spectrum analysis, requires an infinitesimal amount of material and does not require this to be especially purified; the technique is not difficult if appliances for producing high vacua are available ...". It is a reflection on the chemists of the period that it took 30 years for Thomson's predications to be verified.

One difficulty was that the apparatus, simple to a physicist, appeared very complex to a chemist. The application of MS of chemistry had to await the commercial production of instruments. The impetus came in the 1940s when the war effort demanded rapid and accurate hydrocarbon analysis in connection with aviation fuels. The next big step came in the 1950s when it was realized that in addition to quantitative analysis the technique could be used for the qualitative (structural) analysis of organic compounds. A certain resistance had to be overcome to induce mass spectrometrists to put 'dirty' compounds into their instruments rather than 'clean' hydrocarbons. This gave mass spectrometer manufacturers a further impetus to develop more and more advanced instruments and led to a new discipline – organic MS.

Before the advent of the mass spectrometer, the determination of the relative molecular mass (M_r) of an organic compound was performed by quantitative analysis (empirical formula) and a rough M_r was used to decide the number of empirical formula to make up the molecular formula. With the mass spectrometer, the M_r could be determined directly: however, there was more to come. It was noted earlier that the relative atomic masses of atoms were slightly different from integer values. If the M_r of a compound could be accurately determined then there would be only one formula that would be consistent with it. So, it was up to the manufacturers to produce instruments with sufficiently high resolution to be able to separate these values. A word about resolution or resolving power is appropriate here. Although there is no generally accepted definition, one that is widely used is the 10% valley definition. If two peaks of equal height are separated by Δm and the valley between them is 10% of the peak height then the resolving power is said to be $m/\Delta m$. If one considers the doublet at m/z 28 corresponding to C_2H_4 and N_2 , Δm is $(28.031\,299 - 28.006\,158) = 0.025\,141$. Thus, $m/\Delta m = 1114$ and a resolving power of approximately 1000 would be required to separate the two peaks. The search for higher and higher resolution led to the introduction of a double-focusing mass spectrometer. It has been seen that while Aston's mass spectrograph gives velocity focusing, Dempster's mass spectrometer gave direction focusing. Nier and Roberts developed a geometry which ensured both velocity and direction focusing. This geometry formed the basis of the MS9 (Associated Electrical Instruments, AEI) (**Figure 6**) which for many years was the workhorse of the organic mass

Figure 5 A single-focusing mass spectrometer (MS2).

Figure 6 A double-focusing mass spectrometer (MS9).

spectrometrists. Initially, it had resolving power of 10 000 but with modifications this value was raised 10-fold. It became apparent that it would be advantageous if the ion beam could be selected before its subsequent analysis. This gave rise to the ZAB series of mass spectrometers (Vacuum Generators). These instruments also had the advantage of the ion beam being in the horizontal plane (the AEI instruments had the ion beam in the vertical plane) which made it much easier to add additional sectors when required.

Representation of Mass Spectra

The Bar Diagram

Mass spectra are usually represented by bar diagrams on which the relative intensity of peak or the relative abundance of an ion is plotted against the m/z value (Figure 7). The molecular peak $[M]^{\bullet+}$ is the one corresponding to the M_r of the compound and the base peak is the most intense one in the spectrum. A further alternative is the use of the fraction of the total ion current carried by the ion in question. In the early days of MS, the operator had to laboriously develop the trace recorded on photographic paper or equally laboriously plot the ion current against the m/z ratio. More recently, the spectra are electronically recorded and can be plotted out according to the whim of the operator.

The Anatomy of a Mass Spectrometer

The Components of a Mass Spectrometer

The mass spectrometer consists essentially of a source, which produces a beam of ions, an analyser which separates the beam according to the m/z ratio and a collector which determines the fraction of the total ion current carried by each of the ions.

Figure 7 Mass spectrum of $[HCONHC(CH_3)_3]$.

Sector Instruments

The source

Probably, the most widespread method of ion production is by electron impact. The other fundamental, though little-used method, is that of photoionization. In recent years, a number of other methods have been developed, such as fast atom bombardment (FAB) and electrospray (ES) both of which are known as 'soft' methods of ionization in that they transfer relatively little energy to the ion. A bonus with ESMS lies in the fact that multiply charged ions are produced, thus extending the mass range. Thus, for an ion m^{20+} the effective mass range will be 20 times that of a singly charged ion. These two techniques have had considerable application in biological and medical MS. An alternative soft ionization method is to use low-energy electrons in impact ionization. If the measurements are also carried out using a cooled source, the process produces what are known as LELT (low energy, low temperature) spectra.

In the electron impact source, a beam of electrons (usually 70 eV) impacts the gaseous substrate under investigation and removes an electron from it, thus producing an ion. This is a drastic method since ionization energies are usually of the order of 10 eV and chemical energies of the order of a few volts. The processes occurring are as follows:

Process [2] represents ionization to form the molecular ion whereas [3] represents fragmentation to form an even electron ion and [4] represents fragmentation to form an odd electron ion. In writing equations for fragmentation,

it is essential that 'electron bookkeeping' be maintained. What is shown here is primary fragmentation – the ions F^+ can further fragment to give secondary fragments and so on.

The analyser

It has been seen that a transverse magnetic field can separate an unresolved beam of ions according to their m/z values (Figure 5). Such a system gives direction focusing. An electric field (see Figure 6) can give direction focusing and so lead to a double-focusing mass spectrometer capable of high-resolution measurements.

The collector

The usual collector is an electron multiplier which can give gains of 10^7 or more. The output is sent to a recorder or data system. An earlier form is the Faraday cup which collects the electrons – the current then being amplified and recorded.

The Quadrupole

Originally, the tool of physicists and physical chemists, now with improved electronics, the quadrupole mass spectrometer has become an essential instrument for biological and biomedical research. Originally described as a mass filter, it operates by using a combination of a quadrupole static electric field and a radio frequency field which combine to focus an ion beam on a collector.

The Ion Trap

This device is related to the quadrupole, being a three-dimensional quadrupole. The ion trap consists of a hyperbolic ring electrode (doughnut) and two hyperbolic end electrodes. To obtain a spectrum, a variable amplitude radio frequency is applied to the doughnut whilst the end plates are grounded. As the amplitude is increased, ions of increasing m/z are collected.

The Time-of-Flight Mass Spectrometer

In this instrument, ions produced in the source are accelerated to a given velocity. The unresolved beam is then injected into a field-free region (FFR) and the ions drift towards the collector. The velocities will be inversely proportional to the square roots of the masses. This means that a pulse of ions will split up according to the ionic masses. The unresolved beam thus becomes resolved in time. Provided that the response time of the electronics is sufficiently fast, a spectrum can be recorded. Obviously, an average over many such pulses is necessary to provide a reliable signal. Once again the electronics lie at heart of this problem, which demands very fast amplifiers. Initially the time-of-flight (TOF) mass spectrometer was the province of physicists and later of chemists but, with the tremendous advance in electronics, instruments are now produced that are

capable of routine operation by relatively untrained operators.

The Ion Cyclotron Resonance Mass Spectrometer

An ion cyclotron resonance (ICR) spectrometer creates a pulse of ions in a magnetic field. These are brought into resonance by scanning the applied radio frequency. From the cyclotron resonance frequency and the magnetic field strength, the m/z ratio can be calculated. The use of a fast Fourier transform (FT-ICR) refines the method.

The Energetics of Ionization and Fragmentation

The Thermochemistry of Ions

Just as the thermochemistry of neutral molecules has led to an understanding of the structure, stability and kinetics of chemical species, the thermochemistry of ions has led to a corresponding understanding of ionic species in the gas phase. Thus, the enthalpy of formation $\Delta_f H^\circ(M^{\bullet+})$ of the molecular ion is given by eqn [5].

$$\Delta_f H^\circ(M^{\bullet+}) = IE(M) - \Delta_f H^\circ(M) \quad [5]$$

where $IE(M)$ is the ionization energy of the molecule and $\Delta_f H^\circ$ is the enthalpy of formation of the neutral molecules. Holmes and co-workers have published a very useful algorithm for estimating the enthalpies of formation of odd electron ions. Some typical values for hydrocarbons are shown in Table 2. The agreement between experimental and theoretical values is excellent. Often the enthalpies of formation of the substrate molecule are not known and so recourse has to be made to empirical methods such as that of Benson for estimation of the value.

In the case of the even electron ions one has, mainly, to have recourse to experimentally determined values. The enthalpies of formation of the even electron ions are given by eqn [6] where the appearance energy is represented by $AE(F^+)$, with $\Delta_f H^\circ(F^{\bullet+})$, $\Delta_f H^\circ(F^\bullet)$ and $\Delta_f H^\circ(M)$ being the enthalpies of formation of the ion, the

^aEstimated value.

radical and the molecule.

$$\Delta_f H^\circ (F^{\bullet+}) \leq AE(F^+) + \Delta_f H^\circ (F^\bullet) + \Delta_f H^\circ (M) \quad [6]$$

In eqn [6], the inequality may be replaced by the equality in most instances. Some values for the primary carbonium ions are shown in **Table 3**. Values such as these can then be used in calculating ionization and appearance energies. These are, respectively, the lowest energy at which the molecular ion appears and the lowest energy at which a fragment ion appears. Thus, the ionization energy is given by

$$IE = \Delta_f H^\circ (M^{\bullet+}) - \Delta_f H^\circ (M) \quad [5a]$$

on rearranging eqn [5]. Similarly, the appearance energy is obtained by rearranging eqn [6].

$$AE(F^+) = \Delta_f H^\circ (F^{\bullet+}) + \Delta_f H^\circ (F^\bullet) - \Delta_f H^\circ (M) \quad [6a]$$

Holmes and Lossing have developed an ingenious method of measuring the enthalpies of formation of neutrals by a further rearrangement of eqn [6]. This is extremely useful where the enthalpy of formation of the neutral has not been measured. The method depends on measuring the appearance energy of a fragment ion produced from different sources

$$\Delta_f H^\circ (M) = \Delta_f H^\circ (F^{\bullet+}) + \Delta_f H^\circ (F^\bullet) - AE(F^+) \quad [6b]$$

and using the average value in eqn [6b].

Metastable Ions

It will be seen in **Figure 6** that there are two important field-free regions (FFR) in the double-focusing mass spectrometer, namely, between the source and the electric analyser (FFR1) and between the electric and magnetic analysers (FFR2). It may so happen that in flight an ion decomposes in FFR1 in which case a diffuse peak appears in the mass spectrum at the position m/z given by eqn [7]

$$m^*/z = m_2^2/m_1 \quad [7]$$

**Figure 8** A metastable peak in the mass spectrum of anisole.

for process [8]. A typical metastable peak is shown in **Figure 8** for the process

$$m_1^+ = m_2^+ + (m_1 - m_2) \quad [8]$$

The appearance of a metastable peak is confirmation of a fragmentation route, but absence of the peak does not indicate the absence of a fragmentation. The reason is that metastable ions are relatively long lived. If the fragmentation is rapid no metastable peak will be seen. A special scan, keeping B/E constant, will record all the daughter peaks resulting from a given parent ion. Equally, a scan keeping B^2/E constant will give all the progenitors of a given peak. These scans are very useful in mapping out the fragmentation patterns of a given ion.

Collision-Induced Dissociation

Another means of producing fragmentation involves collision processes – bimolecular as compared with the unimolecular processes previously discussed. In this method, a beam of energetic ions is brought into collision with neutral molecules and fragmentation results – collision-induced dissociation (CID). The spectra thus obtained were complex since they derived from an unresolved beam of ions. It was realized that it would be advantageous if the ions for collision were separated from the unresolved beam. This led to

the development of a reversed geometry instrument – the ZAB, produced by Vacuum Generators. Finally, there was the introduction of multisector instruments which gave rise to the technique of MS-MS. CID has proved very useful in assigning structures to fragment ions.

A bright future exists for mass spectrometry, owing to its characteristic features for providing unparalleled sensitivity and structural chemical information. The continued miniaturization of instrumentation will result in smaller and specialized mass spectrometers that will be purpose developed, built, and sited for particular applications (drugs, explosives, isotopic applications). Current trends in hyphenation of mass spectrometry with other techniques (chromatography, NMR, etc) and even among different MS techniques will continue to yield even more unique and powerful MS capabilities. The future development of both electrodynamic and time-of-flight MS techniques offer to provide new approaches to very high spectral, spatial, and temporal resolution modes of mass spectrometry. The development of new magnet technologies also promises to make FT-ICR MS techniques more available and practical for the broader MS community. Thus, the range of types of MS instruments available and the applications of these new instruments promise to keep mass spectrometry a fertile and productive field of research and development for some time to come.

The Literature of Mass Spectrometry

1968 saw the first of the journals devoted to mass spectrometry. *Organic Mass Spectrometry* (OMS) and the *International Journal of Mass Spectrometry and Ion Physics*

(IJMSIP). Later OMS spawned *Biomedical Mass Spectrometry* (BMS). IJMSIP has since changed its name to *The International Journal of Mass Spectrometry and Ion Processes* and latterly to the *International Journal of Mass Spectrometry*, whereas OMS and BMS have been incorporated in the *Journal of Mass Spectrometry*. The American Society for Mass Spectrometry has produced a journal – *Journal of the American Society for Mass Spectrometry*. To facilitate rapid publication, *Rapid Communications in Mass Spectrometry* was born – the authors nominate their own referees.

a_0	Bohr radius
df/dE	differential oscillator strength
E	electron collision energy
i	ionization current (t, total; ms, mass selected)
IE	ionization energy
N_t	number of target particles cm^{-3}
$n(0)_e$	initial electron intensity [$\text{cm}^{-2} \text{s}^{-1}$]
$u (= E/R)$	reduced electron energy [$R = \text{H}$ ionization energy]
W	electron energy after ionization collision
σ	ionization cross section (t, total; c, counting; z_i for ion i of charge ze)
δ	polar angle of outgoing electron

Introduction: Electron Ionization, Photoionization

At the heart of mass spectrometry lies the formation of the ions to be analysed. A thorough understanding of the production of the ions is extremely important, since the method used to ionize a sample markedly affects its mass spectrum (fragmentation pattern). Besides electron impact ionization (EI) and photoionization (PI), a number of different methods are used in mass spectrometry including chemical ionization (CI), field ionization, fast atom bombardment, surface ionization, electrospray ionization, laser ablation and other plasma methods. EI is by far the most common method as it is simple to use, easy to set up and very effective. For instance the maximum ionization cross section (see definition below) for the hydrogen atom is approximately 10^{-20} m^2 (at 100 eV) for electrons as compared to approximately $5 \times 10^{-22} \text{ m}^2$ (at 14 eV) for photons. On the other hand, PI has yielded basic and accurate data required for the understanding of the energetics and dynamics of ionization and fragmentation.

Because of its overwhelming importance in mass spectrometry, only EI (and, to a lesser extent, PI) will be treated here. We will consider the ionization mechanism, the various types of ions produced and the kinetics and

dynamics of the ionization process and subsequent fragmentation reactions.

Electron ionization (EI) is the process by which an atom or a molecule M is ionized by electron impact to form a positive ion (eqn [1]).

Photoionization (PI) is the process by which M is ionized through photon impact.

The *ionization energy* (IE) is the minimum electron energy or photon energy required to produce ionization from M and is related to the binding energy of the most loosely bound valence electron in the molecule. When the electron energy or photon energy is varied continuously there is a threshold energy below which the ion current is zero and above which it rises with increasing energy, according to a particular threshold law (see below). This threshold is an experimental measure of the IE. The IE often (but not always) can be determined spectroscopically as the limit of a series of Rydberg states in which the principal quantum number n of the electron reaches increasingly higher values. The IE can be determined mass spectrometrically even in those cases for which a Rydberg series has not been observed spectroscopically.

The majority of neutral, chemically stable, molecules possess a closed shell. As a result, ionization leads to a radical cation, that is to an odd-electron ion (OE^{*+}). In spectroscopic terms, a neutral singlet state leads to an ionic doublet state.

Ionization Mechanism

EI or PI involves the collision of an electron or photon of sufficient energy with a neutral (or ionized) target particle and the subsequent production of an ion and the respective ejected electron(s). The term ‘electron impact ionization’ is somewhat misleading, because an electron is small compared to the size of a molecule and thus would have difficulty ‘hitting’ any part of an atomic target. It is better to think of the electron as passing close to or even through the atomic target, while in quantum-mechanical terms the wave of the electron interacts with and distorts

the electric field of the atomic system. Electrons accelerated through a potential of several tens of volts have a de Broglie wavelength of ~ 0.1 nm. In this case the wavelength and the molecular dimensions are similar and mutual quantum effects (distortions) occur. The wavelength of a photon required for PI is approximately 100 nm which is much larger than the usual molecular dimension and almost no molecular distortion occurs during ionization. Because of this difference in interaction in the case of EI, the ionizing transition is not strictly vertical (see below) and more states (also taking into account spin conservation from the target to the product ion) can be reached relative to PI.

In addition, electron impact can also give rise to the birth of negative ions (anions). In contrast to the formation of positive ions (cations), direct attachment of the incident electron to a polyatomic target to give a stable anion is rather improbable. The reason is that the energy of the attaching electron and the binding energy (electron affinity) must be taken up (accommodated) in the emerging product (anion). Usually, the excess energy leads either to fragmentation of the anion or to shake-off of the electron (autodetachment); radiative stabilization of this excited anion takes place only with very low probability. One way to produce stable anions by direct electron attachment is to have sufficient gas pressure in the ion source for three-body reactions to occur that remove the excess energy (three-body stabilization).

Ionization Channels

Ionization of atoms results only in the production of singly and multiply charged atomic ions. As the energy deposited by the ionizing agent is increased, the variety and abundance of the ions produced from a specific molecular target will increase, because the ionization process may proceed via different reaction channels, each of which gives rise to characteristic ionized and neutral products. For the simple case of a diatomic molecule AB the corresponding reaction channels are as shown in eqns [3]–[13] where e_s is a 'scattered' electron and e_e is an 'ejected' electron.

Similar reaction channels are possible for PI but there are no scattered electrons and dissociative attachment is only possible for EI. Different and more complex reactions may occur when more complex targets are involved, that is polyatomic molecules or clusters (even including multiple electron collisions and subsequent reactions within the molecular target). Clusters and fullerenes have also been demonstrated to undergo a process of delayed ionization which is akin to thermionic emission in bulk material.

Most of the ionization reactions shown above (e.g. eqns [3]–[6], [11]) can be classified as being due to a direct ionization mechanism in which the ejected and the scattered electrons leave the ion within 10^{-16} s of each other. Conversely, there exist alternative ionization channels (competing with direct ionization) in which either the electrons are ejected one after the other (autoionization) or the molecular ion decays at a later stage (see **Figure 1** and below). The autoionization event (e.g. eqns [7] and [9]) can be described as a two-step reaction: first, a neutral molecule (or atom) is raised to a superexcited state, which can exist for some finite time. Then, radiationless transition into the underlying ionization continuum occurs. Superexcited states exist in principle for every target system except for the hydrogen atom. For molecules, the upper autoionization rate (and hence the ionization cross section) is limited by the characteristic energy-storage mode frequency. In addition, if predissociation (into two neutrals) is faster than autoionization, the latter will not occur at an appreciable rate.

Autoionization by photons is a resonance process. Autoionization complicates the ionization cross-section function (see definition below) at low as well as at high electron energies. PI has been extremely valuable in the quantitative study of autoionization processes both in atomic and in molecular systems. Classical examples involve the photoionization mass spectra of noble gas atoms such as xenon (**Figure 2**) and molecular hydrogen,

Figure 1 Schematic time evolution of EI of a molecule.

Figure 2 Photoionization mass spectrum of xenon between the $^2P_{3/2}$ (ground) and $^2P_{1/2}$ (excited) ionic states, displaying sharp 's'-like and broad 'd'-like resonances. Reproduced with permission of Academic Press from Berkowitz J (1979) *Photoabsorption, Photoionization, and Photoelectron Spectroscopy*, Chapter VI.

H_2 (Figure 3). Xenon has filled 5s and 5p shells. Ionization is initially observed at $h\nu = 12.130$ eV with the ejection of a 5p electron and the formation of the ground $^2P_{3/2}$ state of Xe^+ . In the interval between $^2P_{3/2}$ and its spin-orbit partner $^2P_{1/2}$ (12.12–13.436 eV), autoionization structure is prominent (see Figure 2) owing to Rydberg states converging to $^2P_{1/2}$. One notes sharp $p \rightarrow ns$ transitions and broad ones corresponding to $p \rightarrow nd$ transitions. Autoionization takes place by virtue of a 'spin-flip' mechanism in which J changes from $\frac{1}{2}$ to $\frac{3}{2}$ and Rydberg electron is ejected. Autoionization in the case of molecular hydrogen (Figure 3) involves conversion of vibrational energy into additional electronic excitation of the Rydberg electron. Predissociation competes with autoionization of H_2 .

Franck–Condon Principle

Inelastic collisions between electrons/photons and molecules involve transitions between defined (electronic, vibrational and rotational) molecular states. The energy deposited into the excitation of molecular vibration and

rotation is usually rather small compared with the energy of the electronic transition, at least if one assumes that only one vibrational quantum is excited in a single collision. For example, the greatest separation between a ground and a first excited vibrational state of any molecular ion is that of H_2^+ (0.27 eV), which is small compared with the ionization energy of 15.426 eV. The changes in the vibrational levels from v'' to v' that result in ionization can be described in terms of the Franck–Condon principle.

Qualitatively, the Franck–Condon principle may be summarized as follows. During an electronic transition no (or only negligible) changes occur in the nuclear separation and the velocity of relative nuclear motion. Owing to the large ratio of nuclear to electronic mass and the short interaction time ($\sim 10^{-17}$ s, as compared with $\sim 10^{-13}$ s for a vibration), the point on the upper potential-energy curve (corresponding to the configuration after the transition) lies directly above the starting point on the initial potential-energy curve (vertical transition). This leads to a number of possible electronic transitions, which depend on the relative shapes of the

Figure 3 Relative photoionization and photoabsorption cross sections σ_i and σ_a respectively, for parahydrogen at 78 K. The numbers above peaks in the photoionization data give the value of η_i , the quantum yield of ionization. Reproduced with permission of Academic Press from Berkowitz J (1979) *Photoabsorption, Photoionization and Photoelectron Spectroscopy*, Chapter VI.

potential-energy curves available in a specific system. Several cases can be distinguished. (1) The final accessible level lies within the region of discrete vibrational states of the upper potential-energy curve. The probability that the vibrational quantum number will change depends on the relative positions of the potential-energy curves. (2) The final accessible level not only lies within the region of discrete vibrational states, but includes some part of the continuum. Hence, some of the transitions will lead to dissociation. (3) The final accessible level lies within the continuum of a repulsive state and all transitions lead to dissociation.

The Franck–Condon principle can be used to treat quantitatively the fragmentation of diatomic or pseudo-diatomic molecules at low energies. The cross section for ionization from the vibrational level v'' of the neutral molecule to a vibrational level v' in the ionized molecule is given by the Franck–Condon factor (FCF) which is equal to the square of the overlap integral between the respective vibrational wavefunctions, that is $\text{FCF} = |\langle \psi_{v''} | \psi_{v'} \rangle|^2$. In polyatomic molecules, the two-dimensional potential-energy curves have to be replaced by multidimensional potential-energy hypersurfaces. Although EI and PI proceed without nuclear displacement (Franck–Condon principle), the resulting (excited) polyatomic ion will usually subsequently undergo further internal transitions (e.g. radiationless transfer of energy, that is transitions from one surface to another surface), possibly leading to subsequent unimolecular decomposition (see below). Even with an accurate knowledge of the potential energy surfaces, a detailed description of the evolution of the ionized system is virtually impossible; it is necessary to use statistical theory methods.

Koopman's Theorem; Photoelectron Spectroscopy

The photoionization process (eqn [2]) may be studied by using a fixed photon wavelength $h\nu$ and recording the kinetic energy distribution of the emitted photoelectrons. This is called photoelectron spectroscopy (PES). The photoelectron carries away the difference between the photon energy and the binding energy of the ejected electron (eqn [14]).

$$\varepsilon = h\nu - \text{IE}(\text{M}) \quad [14]$$

where ε is the kinetic energy of the electron and $\text{IE}(\text{M})$ is the ionization energy of the molecule, equal to the binding energy of the photoionized electron. Each ionization energy is approximately equal to the negative eigenvalue of the molecular orbital (MO) from which the electron is ejected. This approximation is known as Koopman's theorem, which is based on the self-consistent field (SCF) model.

The photoelectron spectrum of N_2 (**Figure 4**), obtained with $h\nu = 21.21$ eV, demonstrates what happens upon ionization from the three outermost MOs of the molecule, whose electronic structure is $(1\sigma_g)^2(1\sigma_u)^2(2\sigma_g)^2(2\sigma_u)^2(1\pi_u)^4(3\sigma_g)^2$. Ionization of an electron from a nonbonding orbital leads to an ionic state whose equilibrium internuclear distance is not shifted appreciably with respect to the neutral. The vertical transition, according to the Franck–Condon principle, leads to very little, if any vibrational excitation. The outermost σ_g orbital is very weakly bonding. As a result, the strongest transition observed is from $v'' = 0$ of the neutral to $v' = 0$ of the ion. Furthermore, the vibrational spacing in the $^2\Sigma_g$

ionic state that is produced is 2150 cm^{-1} , only slightly less than in the neutral (2345 cm^{-1}). The second band envelope reached, which is due to the ${}^2\Pi_u$ state, has a much richer vibrational structure, because the π_u electron is ionized from a strongly bonding orbital. This causes the position of the minimum in the potential energy curve to be shifted to a larger internuclear distance in the ion with respect to the neutral, to excitation of a number of vibrational levels in the ion within the vertical Franck–Condon region, and to a rather small vibrational spacing of 1810 cm^{-1} in the ion. Finally, the third band, which is due to formation of the ${}^2\Sigma_u$ state of the ion, demonstrates the ionization of a weakly antibonding electron, with a strong propensity for excitation of the 0–0 transition and with a slightly larger vibrational spacing (2390 cm^{-1}) in the ion as compared to the neutral.

Figure 4 Photoelectron spectrum of N_2 obtained with 21.21 eV incident radiation; electron counts versus electron kinetic energy (upper) and versus IE of N_2 (lower). Reproduced with permission of Oxford University Press from Atkins PW (1986) *Physical Chemistry*, 3rd edn, p 483.

Types of Ions Produced

Parent Ions

Parent ions are positively charged ions produced by reaction [3] through removal of one electron from the neutral precursor. The production of these parent ions relative to that of other ions originating from the same neutral precursor (molecule) depends on the electron or photon energy and on the properties of the neutral molecule. At and just above the IE, only singly charged (parent) ions are produced, but at higher electron energies, other ions (see below) are also observed.

In general, for small molecules the parent ion is the dominant ion at all impact energies, although there are exceptions, such as CCl_4 and CF_4 which have no stable parent ions. Conversely, for large molecules the relative parent-ion abundance usually decreases with increasing molecular mass and increasing incident energy. Again there are exceptions to this rule, the most notable one concerning the fullerenes, where the singly charged C_{60}^+ parent ion is the most abundant ion in the mass spectrum (see Figure 5).

The parent-ion abundance depends also on the temperature of the molecular gas target. At constant ion-source gas pressure a decrease in all ion intensities is noted with increasing temperature, while an increase in vibrational energies of the molecular ion (due to the increase in the vibrational energies of the neutral precursor) may lead to an appreciable decrease in the relative parent-ion intensity. For polyatomic molecules, this latter effect can be explained in terms of statistical theories.

Fragment Ions

If the incident energy is increased above the IE of the molecule, fragment ions appear owing to reaction paths

Figure 5 Mass spectrum of C_{60} ionized with 200 eV electrons.

discussed above in relation to the Franck–Condon principle. In the case of polyatomic molecules, a wide variety of fragmentation channels is available; that is the molecular ion can immediately decay into a fragment ion with an even or odd number of electrons (primary fragment ion). These primary fragment ions may also be produced in (unstable) excited states and immediately decay into further fragments. The number of fragment ions and their relative cross-section functions are characteristic of the corresponding parent molecule. The relative importance of the various ions as a function of internal energy can be demonstrated with the help of breakdown curves (see Figure 6 showing the breakdown graph of propane).

In the case of diatomic parent molecules, the fragmentation can be treated quantitatively in terms of the Franck–Condon principle. For the dissociation of small polyatomic molecules, spectroscopic and quantum-theoretical ideas (correlation rules) can be used to determine the dissociation path and predict the resulting electronic states. With the advent of *ab initio* CI (configuration interaction) calculations, detailed information on the potential energy surfaces of the different states and on their interactions is becoming available. However, to deal with large polyatomic molecules, statistical theories have to be used, that is the so-called quasiequilibrium (QET) theory or an almost identical approach, the so-called RRKM theory (named after Rice, Ramsperger, Kassel and Marcus).

In general, the relative abundance of any fragment ion is related to its rate of formation and its rate of dissociation by unimolecular decomposition. Hence, the measured fragmentation pattern of a molecule is a record in time of the ‘quasiequilibrium’ balance of these rates. In

Figure 6 Breakdown graph of propane. The relative abundances of the ions indicated are plotted as functions of the sum of the IE of propane and the internal energy of the parent propane ion.

other words, because the fragmentation pattern is a slice of the three-dimensional plot of ion current as a function of incident energy and mass-to-charge ratio, the respective partial ionization cross-section functions will depend on the time after formation of the primary ion. Trapped-ion mass spectrometry has been used to investigate this phenomenon for EI and PI. Typical results for short and long delay times are shown for $C_6H_6^{+\bullet}$, $C_6H_5^+$ and $C_6H_4^{+\bullet}$ in Figure 7. The increased fragmentation of $C_6H_6^{+\bullet}$ at long delay times (due to the presence of metastable ions, see below) is obvious.

In this context it is interesting to point out that the reason for running mass spectra at relatively high electron energies (50–100 eV) is that fragmentation patterns do not vary very much with electron energy in this energy range and that the partial ionization cross-section functions (and thus the detection efficiency) have their respective maxima in this energy range (see below). On the other hand, much energy can be transferred to the

Figure 7 Partial ionization cross-section functions for ions of 1,5-hexadiyne (a linear isomer of benzene) at two different detection times, t .

molecular ion in this energy range, resulting in extensive fragmentation (see below), sometimes making it difficult to identify the parent ion. Because of this, EI is considered a 'non-soft' ionization technique compared with PI or CI. However, if similar energies are used for PI and EI, very similar mass spectra are often observed.

Finally, it should be pointed out that dissociative ionization yields fragment ions with small to moderate kinetic energies. To describe the dissociative ionization process completely, these kinematic properties must be known.

Metastable Ions

Ions produced with lifetimes longer than those of excited ions that decompose in the ion source (prior to approximately 10^{-6} s) are called metastable ions. The existence of metastable ions can be explained by different mechanisms depending on the size and property of the precursor ion. Normally, dissociation of an excited ion occurs during the first vibration (prompt dissociation), or predissociation that involves a transition from one potential energy hypersurface to another, which also occurs rapidly; therefore, the product ions are produced in the ion source (see fragment ions). However, if crossings of potential hypersurfaces are spin-forbidden, some ions will nevertheless undergo electronic predissociation but will do so at a reduced rate. Thus, electronic (forbidden) predissociation via repulsive states is one origin of metastable ions. A second possible mechanism is dissociation by tunnelling. In this case the initial excitation is to bound levels of an excited state of the molecular ion that are above the dissociation limit of this state, but below the top of either an intrinsic or centrifugal barrier. The existence of large metastable ions can be rationalized in the framework of QET and is termed vibrational predissociation. After ionization, radiationless transitions yield highly vibrationally excited ground-state ions with a distribution of internal energies and hence a distribution of decay rate constants including those that lead to unimolecular decomposition in the metastable time range.

If the metastable decomposition occurs in flight before the ion reaches the analyser of a mass spectrometer, a typical metastable peak may be observed in the mass spectrum depending on the type of mass analyser used. Moreover, using appropriate methods, it is also possible to deduce the kinetic energy distribution of the nascent fragment ions at these late times after the initial excitation.

Multiply Charged Ions

Multiply charged atomic and molecular ions were observed and identified as early as 1912. Subsequent observation of numerous doubly charged ions followed.

Triply charged molecular ions have been detected in low abundances in the mass spectra of some species (e.g. CO_2 , CS_2 , C_2N_2 and aromatic compounds). Moreover, EI of free van der Waals clusters can lead to multiply charged ions with up to five and more elementary charges. Conversely, with certain molecules (e.g. H_2O and CH_4), it is not possible to detect any stable doubly charged molecular parent ions by EI.

The partial ionization cross sections for the production of multiply charged atoms and molecular ions rarely exceed 1–5% of that of the dominant singly charged ion. Certain atoms and compounds, however, have been found to possess an increased ability to sustain two or even more positive charges, an especially intriguing example being C_{60} (see Figure 5).

Ionization Cross Sections

Definitions

Consider, as shown in Figure 8, a parallel, homogeneous and monoenergetic beam of electrons crossing a semi-infinite medium containing N_t target particles per cubic centimetre at rest. If $n(0)_e$ represents the initial electron intensity (number of electrons per area and per second), the intensity of the electron beam at depth x is given by the exponential absorption law (eqn [15]):

$$n(x)_e = n(0)_e \exp(-N_t \sigma x) \quad [15]$$

If $N_t \sigma x \ll 1$ (single-collision condition), the number of ions generated per second along the collision interaction path $x = L$ (over which the ions are collected and analysed) is

$$n(L)_i = n(0)_e N_t \sigma_c L \quad [16]$$

where σ_c is the counting ionization cross section. The total positive-ion current i_t produced in this interaction volume is given by

$$i_t = n(0)_e e N_t \sigma_t L \quad [17]$$

where σ_t is the total ionization cross section. If the ions produced are analysed with respect to their mass m and

Figure 8 Schematic view of an electron impact ionization experiment.

charge ze , the respective individual ion currents measured with a Faraday cup are given by

$$i_{ms} = n(0)_e ze N_i \sigma_{zi} L \quad [18]$$

where i_{ms} is the mass selected ion current and σ_{zi} is the partial ionization cross section for the production of a specific ion i with charge ze .

Total and counting ionization cross sections of a specific target system are the weighted and the simple sum of the various single and multiple partial cross sections, respectively:

$$\sigma_t = \sum \sigma_{zi} z \text{ and } \sigma_c = \sum \sigma_{zi} \quad [19]$$

Sometimes the macroscopic cross section $s = \sigma N$, which represents the total effective cross-sectional area for ionization of all target molecules in 1 cm^3 of the target medium, is used.

Partial and total ionization cross sections are of great importance for practical applications, but they give only a limited insight into the ionization process itself. Conversely, a great deal of information about the kinematic aspects can be obtained from differential electron ionization cross sections, including the single, double and triple differential cross sections. The single differential cross section $d\sigma(E, W)/dW$, where W is the energy of the electrons after the ionizing collision, measured at the collision energy E , represents the electron energy distribution (integrated over all angles) of the two outgoing electrons. The energy distribution is in principle symmetrical with respect to $\frac{1}{2}(W_1 + W_2) = \frac{1}{2}(E - IE)$, since for each fast electron a corresponding slow electron of complementary energy is ejected. If the incident energy E is large enough, the low-energy part of the distribution is mainly due to 'ejected' electrons and the high-energy part is due to 'scattered' electrons. Although in principle the two outgoing electrons are indistinguishable, this interpretation is supported by the different angular behaviour of these two groups of electrons. Usually, the single differential cross section has a minimum at $W = \frac{1}{2}(W_1 + W_2)$ and maxima close to $W=0$ and $W=(E - IE)$. At very small incident energies, the cross section becomes independent of W (at least for atoms).

The double differential cross section $d^2\sigma(E, W, \delta)/dW d\Omega$ is higher by one order with respect to the number of kinematic parameters, that is the energy W and the polar angle δ of the outgoing electrons have to be measured. In practice, one of the three experimental parameters E , W or δ is varied while the others are kept constant. This allows the determination of either angular distributions (E and W constant) of ejected electrons or energy loss spectra. In general, the higher the energy of the scattered electron, the more their intensity is peaked forward, whereas the angular distribution of very low-energy

electrons is nearly isotropic. The triple differential cross section $d^3\sigma(E, W_1, \delta_1, \delta_2, \varphi_2)/dW d\Omega_1 d\Omega_2$ contains all available kinematic information. It has to be measured in coincidence ('e, 2e experiments') and full graphical representation is impossible.

Ionization Threshold Law

Following the postulates of Wigner that the ionization probability for EI to a first approximation depends critically on the likelihood of the separation step in the exit channel (that is, separation of the collision complex AB^{-*} into a stable ion and two free electrons depends on the probability of disposing of the excess energy), Wannier, using a very simple phase space argument, showed that this probability depends on the number of degrees of freedom n for sharing the excess energy between the electrons, thus giving a threshold law

$$\sigma = k(E - IE)^n \quad [20]$$

For single ionization and thus emission of two electrons, $n=1$ and the coefficients k is determined by the electronic transition probability, which is proportional to the overlap of the vibronic wavefunctions for the neutral ground state and the state of the ion produced. This argument can be extended to z -fold ionization, giving $n=z$. More detailed calculations predict that these power laws should all be increased by 0.127. Using the same arguments for PI, it is then possible to conclude that

$$\frac{d\sigma_{\text{electron}}}{dE} = \sigma_{\text{photon}} \quad [21]$$

Therefore, for single ionization a linear increase of the cross section with electron energy is expected, whereas for direct PI a step-function cross-section law is predicted. This simple theory gives no prediction of the energy range of validity and in practice the threshold laws are slightly different for several reasons, including influence of competitive channels, tailing due to rotational levels, and autoionization which will obscure the true threshold behaviour. Nevertheless, it is customary to assume in accordance with many experimental examples, that for each state of the ion there exists a separate ionization probability described by eqn [20] and that to a first approximation these probabilities are additive (see **Figure 9**). Finally, it is interesting to note that the shape of the threshold law is especially important for the determination of the ionization and appearance energies, because owing to the low ion signal close to the onset it is necessary to invoke an extrapolation method and knowledge of the threshold behaviour facilitates this procedure.

Partial and Total Ionization Cross Sections

As discussed above, there exist different threshold laws for EI and PI. This difference pertains also for higher

Figure 9 Idealized threshold laws for electron impact ionization and photoionization.

energies. Whereas in the case of EI the ionization cross-section function (**Figure 10**) rises more or less linearly over some tens of eV, reaches a maximum at an energy of about 10 eV and then decreases monotonically over some thousands of eV (a logarithmic decrease is predicted in the limit of the Born–Bethe approximation), in the case of PI the abrupt rise at threshold is followed by a monotonic, more or less exponential decline to higher energies (**Figure 11**).

In the limit of zero excess photon energy above threshold, the details of the absorption probability characteristic of the individual targets do not enter and the cross-section function is only dependent on the long-range interaction of the departing particles (electron and positive ion). The Coulomb force then leads to the abrupt onset to a finite cross-section value with a post-threshold behaviour independent of excess photon energy. But even for atomic targets this step function description is inappropriate (see as an example helium in **Figure 11**, which has been studied both experimentally

Figure 10 Experimental (solid symbols) and theoretical (dashed line, distorted-wave Born approximation; full line, Deutsch–Maerk formula and BEB (Binary–Encounter–Bethe) approximation) electron ionization cross section for helium.

Figure 11 Experimental and theoretical (dashed line) photoionization cross sections of helium.

and theoretically). For the heavier noble gases, auto-ionization fine structures due to spin–orbit interaction immediately set in beyond the threshold and thus prevent examination of the isolated continuum (see above and **Figure 2**). For more complicated targets, such as molecular species, additional effects thwart the observation and analysis of the unperturbed continuum. Even the abrupt rise at threshold is not always apparent and therefore step-function behaviour, while a convenient idealization, has little correspondence with reality. A nice example where the step-function behaviour does occur is in the case of the vibrational staircase behaviour of acetylene PI (**Figure 12**).

Inelastic collisions of the electrons with atomic targets are usually divided into two regimes, fast collisions and slow collisions, depending on the relation between the impacting electron velocity to the mean orbital velocity of the electron(s) in the (sub)shell responsible for the inelastic process under consideration. For fast collisions, the influence of the incoming electron upon the target

Figure 12 Mass-selected photoion yield curve of C_2H_2^+ in the vicinity of the ionization threshold. Three steps are observed owing to direct ionization from the vibrational ground state of the neutral to $v = 0, 1$ and 2 of the C–C stretch of the ion. Autoionization structure is superimposed upon the steplike vibrational structure. can be viewed as a sudden and small external perturbation. This concept leads to a cross-section function derived in the Born–Bethe approximation, where the ionization cross-section is given in good accordance with experimental determinations asymptotically by the simple expression

$$\sigma = (4\pi a_0^2/u) M_i^2 \ln(4cu) \quad [22]$$

with a_0 the Bohr radius, $u = E/R$ the reduced electron energy, R the ionization energy of H, $M_i^2 = \int (df/dE)(1/u) dE$ with df/dE the differential oscillator strength and c a collision parameter. It is possible to extract M_i^2 from the slope of a plot of σu versus $\ln(u)$ (Fano-plot).

Conversely, for slow collisions the combined system of incoming electron and target molecule has to be considered, leading in the exit channel to a full three-body problem. Quantum-mechanical (approximate) calculations are difficult and have been carried out only for a few selected examples. Therefore, other methods have been developed with the goal of obtaining reasonably accurate cross sections using either classical or semi-classical theories and by devising semiempirical formulae. Some of these concepts are based on the Born–Bethe formula [22] and on the observation that the ejection of an atomic electron with quantum numbers (n, l) is approximately proportional to the mean-square radius of

Figure 13 Experimental (solid symbols) and theoretical (dashed line, Deutsch–Maerk formula; full line, Binary–encounter–Bethe approximation) total electron ionization cross section for CF_4 .

the electron shell (n, l) . This leads also to proposed correlations of the ionization cross section with polarizability, diamagnetic susceptibility, number of electrons, and the additivity of atomic cross sections to give molecular cross sections. Moreover, there exist simple empirical relations such as between the energy position u_{max} of the maximum cross section and the ionization energy $\sigma_{\text{max}} u_{\text{max}} \approx (R/IE)^2$, which is the high-energy limit of the classical Thomson formula.

Figure 14 Experimental (solid circles and full line) and theoretical K-shell electron ionization cross section for argon: dashed line, Born–Bethe approximation; dash-dotted line, Deutsch–Maerk formula; open circles, Born–Bethe including relativistic corrections.

A particularly useful, simple and versatile formula is the semi-classical Deutsch–Maerk (DM) approach giving the ionization cross section for single ionization σ_i in terms of $\xi_{n,l}$ (the number of equivalent electrons in the (n,l) subshell), $r_{n,l}$ (the electron radius of the (n,l) shell), and some weighting factors $g_{n,l}$. It has been demonstrated recently that this formula may be applied not only to calculate ionization cross sections for ground-state atoms (**Figure 10**), but also for the calculation of cross sections for excited atomic species, for molecules (**Figure 13**), for radicals, for inner-shell ionization (**Figure 14**), for ionization of ions and even clusters, thereby spanning a range of cross-section values from approximately 10^{-34} m^2 for 14-fold ionization of Si all the way up to approximately $5 \times 10^{-19} \text{ m}^2$ for C_{60} and in the case of inner-shell ionization energies from threshold up to 10^9 eV .

The X-ray diffraction technique is widely used in structural characterization of materials and serves as an important complement to electron microscopy, neutron diffraction, optical methods and Rutherford backscattering.

The early uses were mainly in establishing the crystal structures and the phase composition of materials but it has in recent years more and more been used to study stress and strain relationships, to characterize semiconductors, to study interfaces and multilayer devices, to mention a few major application areas.

One of the important advantages of X-ray diffraction is that it is a nondestructive method with penetration from the surfaces into the bulk of the materials. This article will outline some of the most important areas including some rapidly developing fields such as time-dependent phenomena and perturbation studies.

X-ray Sources

X-rays are electromagnetic in nature and atoms have moderate absorption cross-sections for X-ray radiation resulting in moderate energy exchange with the materials studied, making diffraction a nondestructive method, in most cases.

Traditionally X-rays are produced by bombarding anode materials with electrons accelerated by a >30 kV potential. The collision of the accelerated electrons produces a line spectrum superimposed on a continuous spectrum called *bremsstrahlung*.

The line spectrum is characteristic of the bombarded anode material and has photon intensities much higher than the continuous spectrum. The characteristic lines are generated by the relaxation of excited electrons from the electron shells and are labelled K, L, M, etc. and signify the relaxation L to K, M to K, etc.

A table of available laboratory wavelengths is given in Table 1.

The increased importance of X-ray diffraction in materials science is coupled to the emergence of a new source of X-rays based on *synchrotron radiation* storage rings. The synchrotron radiation is produced by the bending of the path of relativistic charged particles, electrons or positrons, by magnets causing an emission of intense electromagnetic radiation in the forward direction of the particles. The photons are generated over a

Table 1 Radiation from common anode materials

Radiation	Wavelength (Å)	Energy (keV)
Ag K _α	0.5608	22.103
Pd K _α	0.5869	21.125

Synchrotron	~0.05–3	4.300

The value α is a mean of the K_{α1} and K_{α2} emissions. The synchrotron radiation is continuous and the range is the most commonly used. The range may be extended on both sides.

**Figure 1** Beam lines at the European Synchrotron Radiation Facility in Grenoble, France.

wide energy range from very long wavelengths in the visible to hard X-rays up to several hundred keV.

The radiation is very intense and exceeds the available normal laboratory sources by up to 6 or 7 orders of magnitude. The synchrotron storage rings used for the radiation production, however, are large and expensive, with facilities characterized by storage rings with a circumference up to more than one thousand metres.

The main advantages of synchrotron radiation are:

1. continuous radiation up to very high energies (>100 keV);
2. high intensity and brightness;
3. pulsed time structure down to picoseconds;
4. high degree of polarization.

Figure 1 illustrates a modern synchrotron facility with many experimental facilities in a variety of scientific areas from atomic physics to medicine.

Figure 2 compares the brightness of the available X-ray sources.

**Figure 2** The brightness defined as photons/s/mm²/mrad²/0.1% energy band pass for conventional and synchrotron X-ray sources. ESRF denotes the European Synchrotron Radiation source in Grenoble, France.

X-ray Diffraction

The diffraction method utilizes the interference of the radiation scattered by atoms in an ordered structure and is therefore limited to studies of materials with long-range order.

The incoming X-ray beam can be characterized as a plane wave of radiation interacting with the electrons of the material under study. The interaction is in the form of both absorption and scattering. The scattering can be thought of as spheres of radiation emerging from the scattering atoms. If the atoms have long-range order, the separate 'spheres' interfere constructively and destructively producing distinct spots, *Bragg reflections*, in certain directions.

The specific scattering angles, θ_{hkl} carry information on the long-range ordering dimensions and the intensity gives information on the location of the electrons within that order.

The basis for all material science studies using X-ray diffraction is Bragg's law:

$$\lambda = 2d_{hkl} \sin(\theta_{hkl}) \quad [1]$$

Figure 3 Reflection from the planes (hkl) with interplanar spacing d_{hkl} .

where λ is the wavelength of the incoming radiation, d_{hkl} is the spacing of the (hkl) atomic plane and θ is the angle of the diffracting plane where constructive interference occurs (see **Figure 3**).

Differentiation of Bragg's law gives the expression:

$$\Delta(\theta) = -\Delta(d)/d \tan(\theta) \quad [2]$$

which is an important formula relating the observed changes in scattering angles to structural changes in the material.

The penetration depth of the probing radiation is an important parameter in designing a diffraction experiment. The penetration depth is associated with the absorption of the radiation, which is a function of the absorption cross-section of the material under study. The absorption can be calculated by the formula:

$$I/I_0 = \exp(-\mu t) \quad [3]$$

where I_0 is the intensity of the incident beam and I is the intensity of a beam having passed through t (cm) of material with an absorption coefficient of μ (cm^{-1}).

The absorption coefficient μ can be calculated as an additive sum over the different atomic species in the unit cell:

$$\mu = 1/V_c \sum (\sigma_n) \quad [4]$$

where V_c is the volume of the unit cell and σ_n is the absorption cross-section for component n . The absorption cross-sections vary as a function of the wavelength and can be calculated using the Victoreen expression:

$$\mu/\rho = C\lambda^3 - D\lambda^4 + \sigma_{K-N}NZ/A \quad [5]$$

where ρ is the density of the material with atomic number Z and the atomic weight A . The constants C , D and $\sigma_{K-N}N$ vary with the wavelength. Tabulations for

Table 2 Penetration depth τ ($1/e$) in Al, Fe and Cu for various techniques in millimetres

	Al	Fe	Cu
Scanning electron microscope	<0.001	<0.001	<0.001
X-ray diffraction (Cu K_α)	0.14	0.007	0.005
Synchrotron X-rays (80 keV)	18	2.1	1.4
Synchrotron X-rays (300 keV)	36	11.5	10
Neutrons (cold)	97	8.3	10

various materials can be found in International Tables for Crystallography, Vol III, pp 161 ff.

It can be noted that the absorption drops off with decreasing wavelength and the penetration depth can thus be changed with a change in wavelength. A quantity called *penetration distance*, τ , is usually quoted for penetration depths and is defined as the distance where I/I_0 is reduced to $1/e$. Penetration distances for a few elements are listed in **Table 2**, together with a comparison with other methods.

Structure Determinations

Historically, and even today, the structure determination of crystalline materials is the most important application of X-ray diffraction in materials science. The relative intensities of Bragg reflections carry information on the location of the electrons in the solids and thus give precise information on the relative positions and thermal motion of the atoms. Even information on the bonding electrons may be obtained.

The scattered intensities from different planes (hkl) in a crystal are measured using precise diffractometers that orient the sample with respect to the incident X-ray beam for all the possible diffraction planes in the crystal. Intensities are measured using scintillation, semiconductor CCD or imaging plate detectors. The measured intensities are converted, after various geometric corrections, to the amplitude structure factors $|F_{hkl}|$ which are proportional to the scattered intensities.

The factors can be expressed as:

$$F_{hkl} = \sum_j f_j \exp\{-2\pi i(au_j + bv_j + cw_j)\} \quad [6]$$

where the f_j are the atomic scattering factors for atoms j and u_j , v_j and w_j are the fractional coordinates for atom j .

The electron density in the crystal unit cell can be determined from the structure factors $F_{hkl} = |F_{hkl}| \times e^{i\phi_{hkl}}$. The structure amplitudes ($|F_{hkl}|$) are obtained from the experiments and the phases ϕ can be obtained from a number of phasing procedures. The structure factors can then be converted to a mapping of the electron density distribution $\rho(xyz)$, which

completely determines the crystal structure.

$$\rho(xyz) = 1/V_c \sum_{hkl} |F_{hkl}| e^{i\phi_{hkl}} \exp(-2\pi(bx + ky + lz)) \quad [7]$$

V_c is the volume of the unit cell and x, y, z are the positional coordinates in the unit cell.

The most precise structure determinations are performed using a single crystal sample where hundred to thousands of separate Bragg spots can be used to determine atomic positions to a precision of better than 0.001 Å. In materials science, however, quite frequently the material is in a polycrystalline form and powder diffraction methods have to be employed.

In the powder diffraction method the Bragg reflections from many thousands of microcrystals with different orientation overlap giving rise to 'powder' diffraction rings rather than distinct Bragg spots. Since the powder patterns are in the form of rings rather than distinct spots (see **Figure 4**) the observed intensities from planes with identical or closely similar scattering angles are analysed in terms of a deconvolution function:

$$Y_i = B_i + \sum_{hkl} I(hkl)Ng \quad [8]$$

where B_i is the background in point i , g is the powder peak shape function and N is a normalization factor. Once a structure model is obtained a refinement procedure proposed by Rietveld can be used to minimize the quantity

$$M = \sum_i W(Y_i(\text{obs}) - Y_i(\text{calc}))^2 \quad [9]$$

where W is a weight factor based on counting statistics. $Y(\text{calc})$ may contain positional, thermal parameters, unit cells as well as peak shapes and these parameters are refined during the minimization.

The method is used for structure determinations and is well suited to handling multiphase systems. At present the method gives bond distances to within ≥ 0.005 Å precision, and *ab initio* structure determinations may handle systems with up to 200 parameters. **Figure 5** gives an example of a powder pattern collected at the European Synchrotron Radiation Facility of a two-phase powder sample.

The broadening of a diffraction line may give important information on changes occurring during the processing of the material. The line width is affected

Figure 4 The left-hand picture illustrates a powder diffraction pattern of S_2N_2 at a wavelength of 0.325 Å. The inset is the actual pattern which can be integrated and displayed as a function of d^* [$d^* = (2 \sin \theta)/\lambda$]. The right-hand picture shows the result if one single S_2N_2 crystal is rotated in the X-ray beam. The size of the spots illustrates the difference in diffracted intensities from the separated Bragg reflections. Courtesy of Svensson and Kvick, 1998.

Figure 5 The powder pattern from a two-phase mixture of orthorhombic $(\text{CH}_3)_2\text{SBr}_{2.5}$ and monoclinic $(\text{CH}_3)_2\text{SBr}_4$ recorded at a wavelength of 0.94718 Å at the BM16 beamline at the ESRF. The two lines of vertical bars show the location of diffraction lines for the two different phases. by instrumental resolution, source size, divergence of the radiation, particle size, microstrain components and stacking faults. After appropriate correction qualitative information on the micrograin size can be obtained by using the Scherrer formula. The grain size affects the line broadening as a function of wavelength and scattering angle as:

$$\Delta 2\theta = \lambda / (D \cos \theta) \quad [10]$$

where D is the particle size.

In order to separate particle broadening from strain effects two or more reflections may be used. The strain varies as function of $\tan \theta$ and the different effects in line broadening may thus be separated by determining the broadening from different (hkl) diffraction lines.

Anomalous Scattering

The absorption and scattering can change considerably around the absorption edges for the atoms. The absorption edge region is the atom specific energy region where the inner electrons are sufficiently excited by the X-rays to leave the atom or to be excited to an upper electronic shell. In this region the atomic scattering factor f_j is modified and is no longer a real property but has, in addition to an extra real term f_j' , an imaginary term f_j'' .

The term in eqn [6] changes to:

$$f_j = f_j^0 + f_j' + if_j'' \quad [11]$$

These changes can be used to alter the absorption and consequently the penetration depth by changing the wavelength around the absorption edges. The changes may be considerable and can amount to the equivalence of tens of electrons.

In addition to changes in absorption there are fundamental differences in the scattering which may be used in materials science. Examples include the determination of absolute optical configuration in polar compounds.

Normally, the Friedel pairs of structure factors, i.e. $F(hkl) = F(-h-k-l)$, are identical. However, around the absorption edges this law breaks down since the imaginary term adds differently in the phase relation and the correct optical isomer can be determined.

The alternation of the scattering for a specific atom may also be used to resolve the partial contribution of that atom at a specific site by multiple wavelength differences studies.

The scattering contrast between almost isoelectronic elements such as Fe and Co may be enhanced sufficiently to allow precise determinations. Small chemical shifts in the energy of the edges depending on the valence state of the atom may also be used to differentiate between the valence states of the atoms in a compound.

The effect is particularly useful for structure determinations of macromolecules where multiple anomalous diffraction (MAD) experiments are combined to yield the phase factors necessary to obtain the electron density mapping.

The use of anomalous diffraction has gained in importance as synchrotron radiation sources have become

available. The synchrotron sources provide easily tuneable radiation covering most of the atomic absorption edges.

Magnetic Scattering

The minute scattering component coming from the magnetic moments of atoms has been exploited more recently. The scattering from the magnetic moments are smaller than the scattering from the electrons by orders of magnitude. However, successful studies of magnetic structures and even magnetic atomic overlayers are now possible by using the high brightness synchrotron sources.

The synchrotron radiation also makes it possible to tune the wavelength to the absorption edges of the magnetic atoms where the magnetic scattering is strongly enhanced. For a more detailed account of anomalous diffraction and magnetism the reader is referred to the book edited by Materlik and co-workers (1994).

Stress and Strain Relationships

Elastic X-ray stress analysis is based on recordings of the interplanar distances d_{hkl} . When stress is applied to a crystal the distances change from d_0 to $d_0 + \Delta d$ and the scattering in Bragg's law (eqn [1]) will change accordingly. Using eqn [2] one obtains the relationship:

$$\Delta\theta = (\theta - \theta_0) = -\Delta d/d_0 \tan(\theta_0) = -\tan(\theta_0)\varepsilon \quad [12]$$

where θ_0 is the scattering angle from a strain-free state, and ε is the elastic strain coefficient. θ is obtained from the diffraction experiment.

In strain analysis the formalism given by Noyen and Cohen (1976) can be used where the strain in the direction of a scattering plane (hkl) is measured as:

$$\varepsilon'(33)_{\phi\varphi} = (d_{\phi\varphi} - d_0)/d_0 \quad [13]$$

The plane spacing d_0 is measured from a strain-free sample.

To obtain the strain in the sample system S one transforms the values from the laboratory coordinate system L.

The orthogonal coordinate systems S_1, S_2, S_3 and L_1, L_2, L_3 are defined as follows. S_3 is perpendicular to the sample surface and S_2 and S_3 are parallel to the sample surface. L_3 is the normal to the scattering plane hkl and makes the angle ϕ with S_3 . The ϕ angle is the angle between the projection of L_3 onto the sample surface and vector S_1 . The measured quantity $\varepsilon_{\phi\varphi}$ can then be converted to the sample coordinate system by the

transformation:

$$\begin{aligned} \varepsilon'(33)_{\phi\varphi} = & \varepsilon_{11} \cos^2\phi \sin^2\varphi + \varepsilon_{12} \sin 2\phi \sin^2\varphi \\ & + \varepsilon_{22} \sin^2\phi \sin^2\varphi \varepsilon_{33} \cos^2\varphi + \varepsilon_{13} \cos\phi \sin^2\varphi \\ & + \varepsilon_{23} \sin\phi \sin^2\varphi \end{aligned} \quad [14]$$

This important equation is linear in $\varepsilon_{11}, \varepsilon_{12}, \varepsilon_{22}, \varepsilon_{33}, \varepsilon_{13}, \varepsilon_{23}$ and these coefficients can thus be determined from six measurements at different angular values. When this is known the stress can be determined.

The stress (σ) and strains (ε) in the sample coordinate system are determined using Hooke's law:

$$\begin{aligned} \sigma_{ij} &= c_{ijkl} \varepsilon_{kl} \\ \varepsilon_{ij} &= s_{ijkl} \sigma_{kl} \end{aligned} \quad [15]$$

where the c_{ijkl} are the elastic stiffness constants and s_{ijkl} are the elastic compliances.

In the elastic case the observations may be expressed in terms of Young's modulus E and Poisson's ratio ν :

$$(d_{\phi\varphi} - d_0)/d_0 = (1 + \nu/E)\sigma_{ij} - (\delta_{ij}\nu/E)\sigma_{kk} \quad [16]$$

where δ_{ij} is the Kronecker delta.

This formalism is the basis for the commonly used $\sin^2\varphi$ method, which is usually limited to the surface region of the sample.

The availability of more elaborate diffractometers and the highly penetrating synchrotron radiation also gives possibilities of deeper penetration into the sample by rotation of the sample around the scattering vector direction, L_3 , and by wavelength tuning or change in the scattering angle. Transmission studies permit the study of stresses in specific 'gauge' volumes in the bulk.

Externally Perturbed Systems

Deformations due to perturbations may also be followed by X-ray diffraction.

These perturbations may be caused by electric field or changes in temperature and thus piezoelectric effects and thermal expansion coefficients may readily be determined by using eqn [2].

In the case of changes occurring from the application of an external electric field, the converse piezoelectric effect, the induced strain coefficient ε_{ij} is related to the field by equation:

$$\varepsilon_{ij} = \sum_{k=1}^3 d_{kij} E_k \quad [17]$$

where E_k is the k th component of the electric field and d_{kij} is the kij th element of the third rank piezoelectric tensor.

Figure 6 The shifts in $\Delta\theta$ for $(00l)$ reflections from a LiNbO_3 single crystal of 0.2 mm thickness subjected to an electric field of 50 kV cm^{-1} along the crystallographic c direction as measured using synchrotron radiation of a wavelength of $0.307 \text{ \AA}$ at the beamline 1D11 at the ESRF. The d_{33} element of the piezoelectric tensor can be evaluated to be $7.5(2) \times 10^{-12} \text{ CN}^{-1}$. Courtesy of Heunen, Graafsma, Kvick, 1997.

Using eqn [2] Barsch has shown that the diffraction observable $\Delta\theta_r$ may be used to determine the piezoelectric tensor according to the formula (Coppens, 1992):

$$\Delta\theta_r = -E \tan \theta_r \sum_{k=1}^3 \sum_{i=1}^3 \sum_{j=1}^3 e_k b_{r,i} b_{r,j} d_{kij} \quad [18]$$

where r refers to certain reflections (hkl) and e_k , $b_{r,i}$ and $b_{r,j}$ are, respectively, the components of unit vectors parallel to the electric field and the scattering vector for (hkl).

Figure 6 gives an illustration where the piezoelectric tensor element d_{33} has been determined from measurements of a series of $00l$ reflections with the electric field aligned along the $(00l)$ direction.

Ion-Implantation Effects

Ion implantation in layers of semiconductor material is an important process where eqn [2] may be very useful for assessing the effect on the implantation.

If dopants are introduced by ion implantation, for instance in silicon, the tetrahedral radius of the dopant (r_d) differs from that of the substrate and changes in the θ angle will be observed.

For cubic silicon material the corresponding change in the unit cell dimension can give information on the doping level according to Vegard's law:

$$\Delta a/a = (1 - r_d/r_s) K C_d N^{-1} \quad [19]$$

where r_d and r_s are the tetrahedral radii of the dopant and substrate respectively, C_d is the concentration of dopant

and N is the number of substrate of atoms per unit volume.

The factor K takes account of the fact that only the lattice strain normal to the wafer is nonzero, whereas the in-plane strain is zero. For typical substrates with cubic structure the K values can be evaluated from the elastic stiffness constants.

Superlattice Structures

Physical properties of materials may be changed by creating 'artificial' structural periodicity by depositing alternate thin layers of different materials. Structures of this type are commonly used in optics, electrooptical applications and coatings for corrosion protection or thermal barriers.

The production and performance of these structures can be characterized by X-ray diffraction. The diffraction patterns from the compound structures are characterized by main diffraction peaks interspersed by satellite peaks. The periodicity of superlattices, Λ , is given by the relationship:

$$\Lambda = (j - k) \lambda / 2(\sin \theta_j - \sin \theta_k) \quad [20]$$

where j and k represent the satellite order number and θ_j and θ_k are the observed scattering angles at wavelength λ . The periods may vary depending on the production and the variation can be monitored by the various Λ values obtained from different satellite pairs. These period variations may be interpreted as surface roughness.

Topography

Diffraction topography is an imaging technique based on Bragg's law (eqn [1]) and ranges from a rather qualitative inspection method of the scattering power over a crystal to a much more complicated method employing dynamical scattering theory to elucidate microscopic strains in the crystal. Many phenomena of importance to a materials scientist, such as stacking faults, growth bands, strain around grain boundaries, twins, or even dynamical phenomena such as acoustic waves or magnetic domain formation, have been studied by this method.

The studies can be divided into two main areas:

- (a) orientation contrast;
- (b) extinction contrast.

The former studies (a) map the variation of the scattering power across the X-ray beam and detect misalignment of certain portions of the crystal where the misalignment is larger than the divergence of the monochromatic incident beam. The misalignment can be due to rotations or dilations of the lattice. When

monochromatic radiation is used these effects are seen as distinct bands or patterns of *loss* of scattered radiation.

A richer pattern of intensity variations is seen if continuous wavelength radiation is used. In this case, due to divergence or convergence of the diffracted beams at the boundaries, *losses and gains* in intensity are observed.

The second phenomenon (b) is observed when the scattering power in the crystal is alternated by strain fields around defects without major realignment in the crystal.

The observed contrasts are rather complicated to quantify and an understanding of the effects of the X-ray wavefields is necessary to interpret the observations in detail. For a detailed account of the theory the reader is referred to Tanner (1976).

Topography uses two different methods of observation; reflection topography, which maps the surface region of the samples, and transmission topography, which also samples the bulk of the material. In the latter case the radiation must be chosen so that the absorption is small enough to allow bulk penetration.

Different volumes in the crystal may be sampled if the collimation of the incident and diffracted beams is carried out carefully. This method is called section topography.

Figure 7 gives an example of the information one may obtain from a transmission topograph.

Time-Resolved Studies

Time-resolved X-ray diffraction has been used for a long time to study solid-state reactions. With the emergence of the new radiation sources it is now possible to follow solid-state reactions, phase transitions and physical changes caused by perturbations on much shorter time-scales.

Topography has already proved to be a suitable technique for studying magnetic domain formation or acoustic deformation down to time-scales of milliseconds.

The use of well-collimated and high-intensity synchrotron radiation beams is essential to reach the necessary time intervals without losing the statistical significance in the observed diffracted intensities. The white beam Laue technique has already been proven to facilitate studies down to the picosecond time regime for studies such as recombination of CO in myoglobin after flash photolysis. Nanosecond resolution has been obtained in a study of laser-annealing of defects in a silicon crystal.

The dynamics of reactions are either reversible or irreversible. Sufficient counting statistics can be obtained in the reversible processes through stroboscopic measurement where repeated measurements using short radiation time slices are performed. In the irreversible experiments the processes have to be followed by rapid consecutive exposures.

Figure 7 Transmission topograph of a flux grown Ga-YIG ($\text{Y}_3\text{Fe}_{5-x}\text{Ga}_x\text{O}_{12}$, $x \approx 1$) crystal plate, Mo $\text{K}_{\alpha 1}$ -radiation ($\lambda = 0.709 \text{ \AA}$). Courtesy of J Baruchel, 1998.

Figure 8 The time-evolution of the powder pattern of an exothermic reaction of a mixture of Al and Ni powders. The powder patterns were recorded at the 1D11 beam line at the ESRF every 250 ms during the self-propagating high-temperature synthesis. The wavelength $0.177 \text{ \AA}$ was chosen to allow penetration of the sample. It can be noticed that the original peaks from Al and Ni disappear or change during the reaction and the formation of new phases and the nucleation can be followed. Courtesy of Kwick, Vaughan, Turillas, Rodriguez, Garcia, 1998.

In many of the cases the reactions are often destructive to large single crystals and the powder method has to be employed. However, it has been proven that reactions such as polymerization and exothermic solid-state reactions may be followed down to the millisecond time-regime even when the reactions are irreversible.

Figure 8 exemplifies the time-evolution of an exothermic reaction between Al and Ni powders. In this time-resolved powder experiment one can follow the initial melting of Al and the formation of intermetallic phases as well as the crystallization process.

The rapid development of fast read-out CCD cameras in combination with the high brightness synchrotron sources promises to give X-ray diffraction a prominent role in the studies of dynamics of processes relevant to materials scientists.

Matrix Isolation Studies by IR and Raman Spectroscopies

Lester Andrews, University of Virginia, Charlottesville, VA, USA

© 1999 Elsevier Ltd. All rights reserved.

This article is reproduced from the previous edition, volume 2, pp 1257–1261, © 1999, Elsevier Ltd.

Matrix isolation is a technique for maintaining molecules in an inert medium at very low temperature for spectroscopic study. This method is particularly well suited for preserving reactive species in a solid environment. Elusive molecular fragments, such as free radicals that may be important intermediates for chemical transformations used in industrial reactions, molecules that are in equilibrium with solids at very high temperatures, weak molecular complexes that may be stable at low temperatures, and molecular ions that are produced in plasma discharges or by high-energy radiation can all be observed and characterized using infrared absorption and laser-excitation spectroscopies. The matrix isolation technique enables spectroscopic data to be obtained for reactive molecular fragments, many of which cannot be studied in the gas phase.

Experimental Apparatus

The experimental apparatus for matrix isolation experiments is designed with the methods of generating the molecular transient and performing the spectroscopy in mind. **Figure 1** is a schematic diagram of the laser-ablation matrix isolation apparatus for infrared absorption spectroscopy. Caesium iodide windows are typically employed. The rotatable cold window is cooled to 4–20 K by closed-cycle refrigeration or liquid helium. The matrix sample is introduced through the spray-on line at rates of 1–5 millimoles per hour; argon is the most widely used matrix gas, although neon, krypton, xenon and nitrogen are also used. In **Figure 1**, the Nd-YAG fundamental at 1064 nm in 5–50 mJ pulses of 10 ns duration is focused (spot size approximately 0.1 mm) onto a rotating metal target. Ablated metal atoms intersect the gas sample during co-deposition on the cold CsI window where collisions and reactions occur. The reactive species can be generated in a number of other ways: mercury arc photolysis of a trapped precursor molecule through the quartz window, evaporation from a Knudsen cell heated inside the chamber, chemical reaction of atoms evaporated from the Knudsen cell with molecules deposited through the spray-on line, and vacuum-ultraviolet photolysis of molecules deposited from the spray-on line by radiation from discharge-excited atoms. For laser excitation studies, the sample is deposited on a tilted copper

wedge which is grazed by the laser beam, and light emitted or scattered at approximately 90° is examined by a spectrograph.

Free Radicals, Anions and Cations

The first free radical stabilized in sufficient concentration for matrix infrared detection was formyl (HCO). Hydrogen iodide (HI) was deposited in a carbon monoxide (CO) matrix and photolysed with a mercury arc; hydrogen atoms produced by dissociation of HI reacted with CO in the cold solid to produce HCO. The infrared spectrum of HCO provided vibrational fundamentals and information about the chemical bonding in this reactive species. Free radicals have been produced in matrices using a variety of techniques such as ultraviolet photolysis (eqn [1]); vacuum ultraviolet photolysis (eqn [2]); lithium atom (eqn [3]); hydrogen atom (eqn [4]); and

Figure 1 Vacuum chamber for infrared matrix isolation studies using laser ablation.

Figure 2 Infrared and Raman spectra of lithium superoxide, Li^+O_2^- , using lithium-7 and 30% $^{18}\text{O}_2$, 50% $^{16}\text{O}^{18}\text{O}$, and 20% $^{16}\text{O}_2$ at concentrations of $\text{Ar}/\text{O}_2 = 100$. The Raman spectrum was recorded using 200 mW of 488-nm excitation at the sample.

lithium atom (and electron) (reaction [5]).

The first molecular ionic species characterized in matrices, Li^+O_2^- , was formed by the co-condensation reaction of lithium (Li) atoms and oxygen (O_2) molecules at high dilution in argon. The infrared spectrum exhibited a weak $(\text{O} \leftrightarrow \text{O})^-$ stretching vibration and two strong $\text{Li}^+ \leftrightarrow \text{O}_2^-$ stretching vibrations, as shown at the top of **Figure 2** for the ^7Li and $^{16,18}\text{O}_2$ isotopic reaction. The 1–2–1 relative-intensity oxygen isotopic triplets in this experiment showed that the oxygen atomic positions in the molecule are equivalent and indicated an isosceles triangular structure. The ionic model for the bonding in Li^+O_2^- was confirmed by contrasting intensities between the laser-Raman and infrared absorption spectra shown in **Figure 2**. Infrared intensities depend upon a change in molecular dipole moment and Raman intensities depend on a change in molecular polarizability during the vibration. Hence, modes between ions ($\text{Li}^+ \leftrightarrow \text{O}_2^-$) will be strong in the infrared and modes within an ion ($\text{O} \leftrightarrow \text{O}$) will be strong in the Raman spectrum. **Table 1** lists the observed frequencies. The contrasting frequencies when Li^+ is replaced by Cs^+ verify the ionic model for the bonding in the $(\text{M}^+)(\text{O}_2^-)$ molecules.

High-temperature molecules like lithium fluoride (LiF) can be trapped in matrices by evaporating the molecule from the crystalline solid in a Knudsen cell at

Table 1 Fundamental frequencies (cm^{-1}) assigned to the ν_1 intraionic and ν_2 and ν_3 interionic modes of the C_{2v} alkali metal superoxide molecules in solid argon

Molecule	ν_1	ν_2	ν_3

CsO_2	1115.6	236.5	268.6

high temperature or by reacting lithium atoms with fluorine molecules during condensation. The latter method has been used to synthesize the calcium oxide (CaO) molecule from the calcium atom–ozone reaction, which gives the calcium ozonide ion pair Ca^+O_3^- and CaO diatomic products.

Continuous exposure of a condensing sample to argon-resonance radiation during sample condensation has been used to produce molecular cations for spectroscopic study. In the case of fluoroform (CHF_3), photolysis produced the $\text{CF}_3^\bullet$ radical, which may be photoionized by a second 11.6-eV photon to give CF_3^+ . The infrared spectrum of CF_3^+ revealed a very high C–F vibrational fundamental, which indicates substantial pi bonding in the planar carbocation.

Complexes

Molecular complexes involving hydrogen fluoride (HF) serve as useful prototypes for the understanding of the important phenomenon of hydrogen bonding. An interesting chemical case is ammonia (NH_3) and HF , which on the macroscopic scale produce the salt ammonium fluoride but on the microscopic scale give the $\text{NH}_3\text{--HF}$ complex. The infrared spectrum of this complex reveals vibrations for NH_3 and HF perturbed by their association in the complex. Fourier-transform infrared spectroscopy is particularly advantageous in these studies because of the high vibrational frequencies for HF species and low sample transmission in this region. The ammonia symmetric bending motion is considerably blueshifted, and the hydrogen fluoride stretching fundamental is markedly redshifted. These shifts attest to a strong intermolecular interaction within the complex.

Ozone (O_3) is a very important molecule in the upper atmosphere, as it absorbs harmful ultraviolet radiation. In the laboratory, this ultraviolet dissociation of ozone provides oxygen atoms for chemical reactions, but in complexes red light can induce an O-atom transfer. Photochemical reactions of elemental phosphorus (P_4), an extremely reactive molecule well suited for matrix

Figure 3 Infrared spectra for laser-ablated Ti atoms and electrons co-deposited with O₂ (0.5%) in excess argon for 45 min at 7 K.

isolation studies, and ozone produce a new low oxide of phosphorus, P₄O, which is involved as a reactive intermediate in the striking of a match. The infrared spectrum of P₄O shows a strong terminal PO bond stretching fundamental and characterizes the P₄O structure as tetrahedral P₄ with an O atom cap. Further photochemical reactions of phosphorus and oxygen produce and trap the reactive molecule [•]PO₂, isoelectronic with the pollutant molecule [•]NO₂, which can also be formed by laser evaporation of red phosphorus followed by reaction with a stream of oxygen gas.

High Temperature Molecules

Titanium dioxide is a white solid used as a pigment in paints, but at 2200–2400 K some TiO and OTiO molecules exist in equilibrium with the solid. The OTiO

molecule is bent ($113 \pm 3^\circ$) with two strong double bonds. The TiO and OTiO molecules have been prepared by reacting laser-ablated Ti atoms with O₂ and trapped in solid argon for infrared spectroscopic analysis. **Figure 3** shows the spectrum of a sample prepared by reacting laser-ablated Ti with O₂ (0.5%) in excess argon followed by condensation at 7 K. The weak 1039.5 cm⁻¹ band is due to ozone which is made by combination of O₂ and O atoms produced in the ablation process. The weak 953.7 cm⁻¹ band is due to O₄⁻ formed by combination of O₂ and O₂⁻, the latter from capture of electrons by dioxygen. The strongest bands at 946.7 and 917.0 (TiO₂) and two weaker bands at 1012.8 (TiO⁺) and 987.8 cm⁻¹ (TiO) are important products. The reaction was repeated for ¹⁸O₂ and mixtures of ¹⁶O₂, ¹⁶O¹⁸O, ¹⁸O₂. **Table 2** lists the isotopic frequencies for these molecules. The 16/18 isotopic ratio is characteristic of the normal vibrational mode. Note that the 917.0 cm⁻¹ band is strong enough to exhibit satellite absorptions at 923.1, 919.9, 914.1 and 911.3 cm⁻¹ that are due to the minor ⁴⁶Ti, ⁴⁷Ti, ⁴⁹Ti and

Table 2 Major infrared absorptions (cm^{-1}) observed for laser-ablated titanium and dioxygen reaction products isolated in solid argon

987.8	946.0	1.0442	TiO
953.7	901.6	1.0578	O_4^-
946.9	904.5	1.0469	$^{48}\text{TiO}_2(\nu_1)$
917.1	881.7	1.0401	$^{48}\text{TiO}_2(\nu_3)$

^{50}Ti isotopes in natural abundance around the major $^{48}\text{TiO}_2$ isotopic band.

The 946.7 and 917.0 cm^{-1} bands form triplet patterns in the statistical mixed isotopic experiment, which verifies the participation of two equivalent oxygen atoms, whereas the 1012.9 and 987.9 cm^{-1} bands form doublets, which shows that a single oxygen atom is involved.

The 946.7 and 917.0 cm^{-1} bands are due to the symmetric (ν_1) and antisymmetric (ν_3) Ti-O stretching fundamentals of OTiO . Titanium isotopic substitution provides a basis for calculation of a lower limit ($111 \pm 3^\circ$) to the OTiO valence angle whereas oxygen isotopic replacement gives a $115 \pm 3^\circ$ upper limit to this angle owing to different anharmonicities. The true angle ($113 \pm 3^\circ$) is the median of these limits.

The 16/18 oxygen isotopic ratios for the 987.8 and 1012.9 cm^{-1} bands are different from values for the above frequencies. These ratios (1.0442 and 1.0443) approach the harmonic value (1.0446) for diatomic TiO . The 987.8 cm^{-1} band is due to TiO in solid argon, which is redshifted from the 1000.0 cm^{-1} gas phase value, and the 1012.9 cm^{-1} band is due to TiO^+ , which has not yet been observed by gas phase optical spectroscopy.

The use of pulsed-laser ablation to produce new chemical species for spectroscopic study is further illustrated for the vanadium atom reaction with N_2 . Laser-ablated metal atoms are sufficiently energetic to dissociate molecular N_2 into N atoms for reaction to form metal nitrides. A sample of 2% $^{14}\text{N}_2 + 2\%$ $^{15}\text{N}_2$ in argon was reacted with laser-ablated V atoms, and spectra from this experiment are shown in **Figure 4**. Four very weak bands ($A = \text{absorbance} = 0.002$ to 0.001) were observed at 1026.2, 1010.3, 1014.4 and 1010.6 cm^{-1} from nitrogen-14 with an identical set at 999.4, 993.6, 987.9 and 984.2 cm^{-1} from nitrogen-15 on sample co-deposition at 10 K (**Figure 4a**). Annealing to 25 and 30 K to allow diffusion and further reaction of trapped species slightly decreased the first band and increased the second, third and fourth bands in each set, and produced new weak bands at 997.8 and 971.4 cm^{-1} (**Figure 4b,c**). Broadband photolysis decreased the lowest two bands and increased the second band in each set. Further annealing to 40 K decreased the first three bands, increased a 1002.8 cm^{-1} band (and 976.5 cm^{-1} counterpart) and increased the final 997.8 and

Figure 4 Infrared spectra in the 1040–960 cm^{-1} region for laser-ablated V atoms co-deposited with nitrogen. (a) 2% $^{14}\text{N}_2 + 2\%$ $^{15}\text{N}_2$ in argon co-deposited at 7 K for 1 h, (b) after annealing to 25 K, (c) after annealing to 30 K, (d) after annealing to 40 K, (e) after annealing to 43 K, (f) pure $^{14}\text{N}_2 + ^{15}\text{N}_2$ co-deposited at 10–11 K for 1 h, and (g) after annealing to 30 K.

971.4 cm^{-1} bands (**Figure 4d**). A final annealing to 43 K destroyed the first two bands and increased the last two bands in each set (**Figure 4e**). One experiment was done with a pure dinitrogen $^{14}\text{N}_2 + ^{15}\text{N}_2$ mixture and the spectra are shown at the top of **Figure 4f** and **4g** for deposition at 10 K and annealing to 30 K; note growth of the strong 997.0 and 970.6 cm^{-1} bands and satellites.

The VN example illustrates how the isolated VN molecule becomes successively ligated by dinitrogen to form $(\text{NN})_x\text{VN}$ on annealing in the solid argon matrix or on deposition in pure dinitrogen matrix. The sharp weak new band at 1026.2 cm^{-1} in solid argon decreases on stepwise annealing while sharp bands increase at 1020.3, 1014.4 and ultimately 997.8 cm^{-1} . These bands exhibit sharp nitrogen-15 counterparts at 999.4, 993.6, 987.9 and 971.4 cm^{-1} , which define nitrogen 14/15 frequency ratios 1.0268, 1.0269, 1.0268 and 1.0272, respectively. These values are in excellent agreement with the harmonic VN diatomic ratio (1.0272) and attest to the pure V-N stretching character of these adsorptions. These bands

showed no intermediate components with discharged (statistical) mixed isotopic dinitrogen, so a single nitrogen atom is involved in these vibrations. In solid dinitrogen, a sharp isotopic doublet at 997.0 and 970.6 cm^{-1} also increased on annealing and revealed the diatomic ratio (1.0272) and is only 0.8 cm^{-1} lower than the dominant nitrogen isotopic doublet surviving past 40 K annealing in solid argon (**Figure 4**).

The sharp 1026.2 cm^{-1} band is due to the VN diatomic molecule isolated in argon. The evolution of bands in **Figure 4** from 1026.2 cm^{-1} to 997.8 cm^{-1} on annealing in solid argon and the 997.0 cm^{-1} band in solid nitrogen provides a convincing picture for the attachment of dinitrogen ligands to the VN center. We note the appearance of five distinct bands for different ligated species. These are consistent with the eighteen electron rule in that these bands are due to $(\text{NN})_x\text{VN}$ with $x = 1, 2, 3, 4, 5$ where the maximum ligated species has eighteen electrons in the valence shell about vanadium.

Mass spectrometry has a wide breadth of application in medicine. This is largely by virtue of having the uncommon ability to combine great sensitivity and specificity with near-perfect generality. Among the most common applications of mass spectrometry in medicine are the diagnosis and confirmation of known acquired and inherited metabolic disorders, characterization and investigation of those previously unknown, and the identification of intoxicants, whether inadvertently or deliberately administered. The use of mass spectrometry (MS), coupled with either gas chromatography (GC) or liquid chromatography (LC), as a metabolic profiling tool (metabonomics, metabolomics) is also increasing, with applications in disease diagnosis and drug safety evaluation. While this article will focus on the area of metabolic disease, the techniques described in brief here can be, and are, applied in a myriad other routine clinical situations. Some of these are measurement of serum homocysteine and methylmalonic acid as an indicator of increased risk for cardiovascular disease, and diagnosis of peptic ulcer, gastritis and gastric cancer caused by *Helicobacter pylori* by measurement of ^{13}C -labelled carbon dioxide released by *H. pylori* from an oral dose of ^{13}C -labelled urea. Mass spectrometry is the 'gold standard' in the clinical laboratory, and is at the heart of many reference methodologies. Serum cholesterol determinations are highly dependent on the natures of the wet chemistries used, and mass spectrometry with gas or liquid chromatographic or capillary electrophoretic inlets provide the only direct and unambiguous measurements available today. Metabolic disease investigation by mass spectrometry, then, is selected only as an example or model of how it may be applied routinely elsewhere in the clinical setting.

Metabolic Diseases

The identification of accumulating metabolites characteristic of a metabolic disease employs mass spectrometry in a qualitative manner. Compounds are identified in a fingerprint sense by computer-comparison of the mass spectra of unknowns with a library of reference spectra either purchased with the instrument or accumulated in-house from reference compounds. Mass spectrometry may also be used in a quantitative sense for the purpose

of monitoring or evaluating patients, usually as part of a treatment protocol.

The most significant metabolic disorders are life threatening in the neonatal period if left untreated and are usually the result of the inherited inability to catabolize normal substrates derived from diet or from normal tissue degradation and recycling. The typical catabolic pathway can be represented by eqn [1],

where A, B, ..., N are precursors, intermediates and final products, and subscripted Es are the enzymes or enzyme complexes that effect the changes associated with each metabolic step. A metabolic disease is said to occur when one (or more) of these enzyme-mediated steps fails to produce the required transformation, and the blood and tissue concentrations of the substrate or precursor for that step (or earlier steps) increase to levels that are toxic, inhibit other enzyme systems or significantly alter the pH or other characteristics of blood or tissues and adversely affect the patient's well-being. Other disorders may be the result of the inability to synthesize a required substance or the inability to transport something essential across a membrane. Identification of accumulating or missing substrates is therefore crucial to understanding the nature of the disorder and the eventual identification of the faulty enzyme or enzyme system.

The list of inherited metabolic diseases continues to grow, and over 500 distinct disorders have been at least partially characterized, with the sequences of the responsible defective proteins known for many of them. Most of these disorders are very rare; the incidence of a given disorder may vary from 1 live birth in 500 000 to 1 in 750, and is frequently dependent upon the degree to which an isolated population is inbred. A paediatrician may spend a lifetime in practice and not encounter any but the most common of these rare diseases.

Diagnosis in the very early postnatal period is critically important if the newborn is to survive and not suffer toxic accumulations of metabolites that frequently lead to retardation of physical and intellectual development. Through correct early diagnosis of many diseases that result from errors of catabolism of dietary components, such as amino acids, diets restricted in these precursors may be instituted to prevent these accumulations.

Diagnosis *in utero* is often achieved by the mass spectral analysis of a small sample of the amniotic fluid for elevations of metabolites excreted by a possibly affected fetus. This invasive procedure is usually only applied when there is a reason to suspect that a fetus may be affected, such as a defect occurring in a prior birth. This provides a basis for an informed decision to be made either to terminate the pregnancy or to prepare for supportive intervention at birth.

The failure of an enzyme may be partial or complete, permanent or transitory. A genetic mutation that encodes for an enzyme that is partially or completely inactive will result in a permanent deficit. Some enzyme deficits that are due to mutations that lead to inefficient binding of a cofactor can be stimulated to a useful capacity by administration of large doses of the cofactor on a life-long basis.

Gas Chromatography–Mass Spectrometry

The use of mass spectrometry in medicine was greatly facilitated by the development of coupled GC-MS. The first commercially successful GC-MS, the LKB-9000, became available in the mid-1960s, and it is estimated that fully half of the inherited metabolic disorders initially described in the 1960s and 1970s were discovered and investigated with various versions of this instrument. Direct coupling of fused-silica capillary columns to a proliferation of small and inexpensive bench-top quadrupole and ion trap instruments has now made practical the screening for metabolic disease in every live birth in developed countries.

An example of an inherited disorder that is the result of a permanent enzyme deficit is methylmalonic acidemia, in which methylmalonic acid (MMA), derived in large part from valine and isoleucine, accumulates. In one of the common forms of this disorder, methylmalonyl-coenzyme A mutase, the enzyme responsible for conversion of methylmalonyl-coenzyme A (CoA) to succinyl-CoA is partially or completely inactive, and the clinical result is a severe and life-threatening keto acidosis, accompanied by high concentrations of MMA in the blood and in tissues and the urinary excretion of up to several grams of MMA per day. In other forms, mutase activity can be increased by administration of large doses of vitamin B₁₂ or one of its related cobalamins, which are necessary cofactors for the mutase. For diagnostic purposes, a sample of urine is collected from the patient and an extract is prepared containing the carboxylic acids present in the urine. The dried extract is treated with a chemical reagent that produces the trimethylsilyl (TMS) esters of the carboxylic acids, and this mixture is then analysed by capillary GC-MS. **Figure 1** is an organic acid profile obtained in this manner, and is an example of the use of GC-MS in the diagnosis of a mutase deficiency. Clearly evident is a very large GC peak due to bis(trimethylsilyl) methylmalonate. Other acids present and identified are normally found in human urine. **Table 1** lists the identities of the eluting peaks in this figure and in the other profiles presented below.

Integrated ion-current peak areas can be related to the quantities of metabolites present in the extract. While relative sensitivities for ionization must be known and taken into account for precise determinations, frequently

Figure 1 The electron ionization total ion current chromatogram for the trimethylsilyl derivatives of the organic acids extracted from the urine of a patient with an inherited error of methylmalonyl-CoA mutase. The major acidic component is methylmalonic acid. The annotated peaks are identified in **Table 1**.

one is forced to assume equality for all metabolites identified when these are unknown. The result is usually accurate to within a factor of 2 or 3 and is sufficient for screening of large numbers of samples.

When more precise measurements are required, stable-isotope dilution techniques are employed. In this approach to quantitation, a measured amount of a stable-isotope-labelled analogue of the compound of interest (internal standard) is added to the fluid to be analysed. The sample is then prepared for analysis and the mass spectrometer is used to report the ratio of the unlabelled to labelled analogues. With relatively few and minor corrections applied, the concentration of the unlabelled metabolite is easily determined. The technique is insensitive to losses in sample separations and variable derivatization yields as these will affect both analogues in the same proportion. As an example, **Figure 2** illustrates the use of this technique in the accurate determination of the concentration of MMA in human serum.

The internal standard is 20 µg of [*Me*-²H₃]MMA, which was added to 1 mL of serum. The acidic extract was converted to the TMS derivatives and analysed in a GC-MS mode termed 'selected-ion monitoring', in which the quadrupole analyser is stepped discontinuously between

Figure 2 Selected ion monitoring analysis of serum for methylmalonic acid. The *m/z* 218.2 ion represents the [*M* – CO₂]⁺ McLafferty fragment of the TMS derivative of endogenous unlabelled methylmalonic acid. The *m/z* 221.2 ion is the fragment derived by a similar process from the internal standard [*Me*-²H₃] methylmalonic acid. The areas integrated for the ions are related to the relative concentration of the derivatives (see text). The deuterium-labelled analogue has a slightly shorter retention time than the unlabelled analogue, a phenomenon perhaps unexpected but commonly observed in these circumstances.

selected ions and reports only their intensities. In this case, the ions selected have masses 218.2 and 221.2 Da, which are moderately intense, characteristic and distinguishing fragment ions in the spectra of the TMS derivatives of MMA and $[Me-^2H_3]MMA$, respectively. The data are obtained as plots of the intensities of these two ions as functions of GC retention time, and resemble independent gas chromatograms for these two fragment ions. The peak areas are integrated and a correction of the 218.2 area is made for isotopic impurity in the internal standard. The 221.2 area is also corrected for natural-abundance heavy isotope inclusion in the light ion that is present as an $M+3$ signal at 221.2. From these calculations one may then conclude that the serum sample was 20.06 μM in MMA, about 10-fold greater than the normal upper limit.

Another inherited error of valine, isoleucine and leucine metabolism is branched-chain α -keto aciduria, also known as maple syrup urine disease because the odour of urine of these patients resembles that of maple syrup. Branched-chain α -keto acid dehydrogenase, the enzyme complex that is used to oxidatively decarboxylate 2-ketoisovaleric, 2-keto-3-methylvaleric and 2-ketocaproic acids to the corresponding branched-chain CoA esters is defective, and very high concentrations of these keto acids accumulate in the blood and urine of these patients. They also have in their fluids large elevations of the corresponding 2-hydroxy acids made by reduction of the keto acids, probably by lactate dehydrogenase. In sample preparation, addition of sodium borohydride to the urine will reduce the three 2-keto acids to the corresponding three 2-hydroxy acids and eliminate (*E*) and (*Z*) isomerism in the TMS derivatives of the enols of the

2-keto acids, thereby simplifying the gas chromatogram. If sodium borodeuteride is added instead, the 2-hydroxy acids that are produced will bear single deuterium substitutions on carbon-2 (eqn [2]) and the labelled/unlabelled ratios may be determined easily for each of the 2-hydroxy acids.

These three ratios then represent the ratios of the 2-keto acids originally in the sample to their corresponding 2-hydroxy acids. **Figure 3** illustrates the urinary organic acid profile of one of these patients after reduction of the urinary 2-keto acids by sodium borodeuteride to the labelled 2-hydroxy acids. The keto/hydroxy ratios are clinically significant as they are related to the $NAD^+/NADH$ status of these patients. ($NAD^+/NADH$ = the oxidized/reduced forms of nicotinamide-adenine dinucleotide.)

A transitory enzyme deficit is one that arises commonly as the result of the ingestion of a toxic material that is or can be metabolized to a suicide substrate for that enzyme, which if depleted must be replaced by *de novo* synthesis. Another common temporary deficit is the result of an immature enzyme system in the newborn that spontaneously resolves itself within a few days.

As an example of the former, Jamaican vomiting sickness presents with severe hypoglycaemia and acidosis that resembles known types of inherited acyl-CoA dehydrogenase deficiencies. The disorder is precipitated

Figure 3 The total ion current chromatogram obtained for the organic acids isolated from the sodium borodeuteride-treated urine of a patient with maple syrup urine disease. The ratios of the 2H -labelled to unlabelled analogues for 2-hydroxyisovaleric acid, 2-hydroxyisocaproic acid and the two 2-hydroxy-3-methylvaleric acid diastereomers are respectively 0.24, 34.5, 30.0 and 3.70.

by consuming the unripe fruit of the akee plant that grows in the Caribbean area. The protoxin is an amino acid, hypoglycine A (α -amino- β -(2-methylenecyclopropyl)propionic acid), which is metabolically converted to methylenecyclopropylacetic acid that irreversibly binds covalently to the flavin moiety of several acyl-CoA dehydrogenases and acts as a suicide substrate to permanently disable their active sites. Treatment is usually limited to supportive care during the period in which the inactivated enzyme system is replaced by new synthesis. The organic acid profile is dominated by very large concentrations of butyric, isovaleric and 2-methylbutyric acids, whose CoA esters require active dehydrogenases for further catabolism to crotonyl-CoA, 3-methylcrotonyl-CoA and 2-methylcrotonyl-CoA esters. Often these acids and other short-chain acids are also esterified to carnitine and excreted in the urine in easily detected amounts.

An example of a transient deficit that is the result of an immature enzyme system is a disorder in which the identification of increased concentrations of tyrosine and 4-hydroxyphenylpyruvic acid (4-HPPA) in urine of a premature newborn would suggest reduced activity of 4-HPPA oxidase. Administration of pharmacological doses of ascorbic acid, the cofactor required for activity of this enzyme, may overcome the temporary oxidase deficit and stimulate catabolism of the accumulating 4-HPPA. **Figure 4** is an illustration of this disorder, which is termed transient neonatal tyrosinaemia.

In addition to increased excretion of 4-HPPA, present here as the oxime, elevations of 4-hydroxyphenyllactic and 4-hydroxyphenylacetic acids are noted, and these are

metabolites that are not important in normal catabolism and are derived from 4-HPPA by other enzymes. The oximes are made by addition of hydroxylamine hydrochloride to the urine during sample preparation for the purpose of detecting succinylacetone (see below).

Tyrosinaemia has an inherited form that is permanent and is due to inactive fumarylacetoacetate (FAA) hydrolase. As a result, FAA accumulates and is enzymatically converted into succinylacetoacetate (SAA), very low levels of which in turn severely inhibit 4-HPPA-oxidase. Many of the same accumulations seen in the transient neonatal form are measured as a result (**Figure 5**).

N-Acetyltyrosine is often noted in these organic acid profiles obtained for the hereditary form of tyrosinaemia, the result of *N*-acetylation occurring when blood levels of tyrosine rise to very high values. As a further complication, succinylacetone (SA), a spontaneous decomposition product of SAA, markedly inhibits porphobilinogen synthetase and other enzymes, which leads to the large number of clinical presentations seen in this disorder. To distinguish the transient and inherited forms, one needs only to measure the serum concentration of SA. SA is unstable to the usual sample preparation methods and, to avoid losses, the oxime is made by addition of hydroxylamine hydrochloride to the serum or urine sample. Since all of the hydrogen atoms in SA are easily exchanged with aqueous protons, no deuterium-labelled analogue of SA resistant to back-exchange can be made for use as an internal standard, and synthesis of a suitably ^{13}C -substituted analogue would be very difficult. This problem can be side-stepped by using 2-methoxybenzoic acid as the internal standard, as this

Figure 4 The urinary organic acids excreted by a premature infant with immature 4-hydroxyphenylpyruvic acid oxidase. This disorder, also known as transient neonatal tyrosinaemia, is characterized by excretion of elevated amounts of 4-hydroxyphenylacetic, 4-hydroxyphenyllactic and 4-hydroxyphenylpyruvic acids. The urine was pretreated with hydroxylamine hydrochloride, which converts the keto acids into the respective oximes.

Figure 5 The organic acid profile obtained for a patient with inherited tyrosinaemia. Very large concentrations of 4-hydroxyphenyllactic acid and *N*-acetyltyrosine are in evidence.

does not occur in human metabolism and it elutes without interference by an endogenous metabolite. Ions selected for monitoring are m/z 209.1 and 212.1, the $[M-CH_3]^+$ fragments of the TMS derivatives of 2-methoxybenzoic acid and the positional isomers 3-[5-(3-methylisoxazolyl)] propionic acid and 3-[3-(5-methylisoxazolyl)] propionic acid. The latter two compounds are produced in the oxidation of SA, and while they are separable on gas chromatography they are summed for quantitation. **Figure 6** illustrates an example of such an analysis of a urine sample.

Hence, this example represents the use of an unrelated compound as the internal standard, 2-methoxybenzoic acid in this case. It is necessary in these circumstances to carefully prepare calibration curves with samples of known composition to take into account the relatively different extraction and ionization efficiencies and appearance potentials for the ions selected.

Fast Atom Bombardment and Electrospray Ionization

Several diseases are known that result in elevations in tissues and fluids of various esters of carnitine and reduce the availability of free carnitine, which is normally synthesized by humans and is necessary for the transport of long-chain fatty acids into mitochondria for oxidation. In several disorders arising from acyl-CoA dehydrogenase deficiencies, the accumulation of the acyl-CoA substrate frequently sequesters coenzyme A and reduces its availability for other unrelated but important and otherwise competent pathways. Carnitine administration can displace and make available much of the coenzyme A

that had been isolated, and stimulate the excretion of the accumulating acidic metabolites now esterified to carnitine. Detection of reduced levels of serum or urinary free carnitine and elevations of esterified carnitine is therefore useful for diagnosis of a variety of metabolic disorders, among them a congenital inability to synthesize carnitine. In this disorder, carnitine must be supplied by a carnitine-enriched diet as it is, in effect, a vitamin.

Carnitine and its esters (see [3]) cannot be introduced to the mass spectrometer by gas chromatography, as they incorporate quaternary amine functions and will decompose in the attempt. Fast atom bombardment (FAB) and electrospray ionization (ESI) can use the formal charge on the quaternary amine function to advantage, as carnitine and its esters are very easily desorbed from glycerol on the FAB probe and from aerosol sprays in ESI. **Figure 7a** illustrates the use of FAB in the quantitation of carnitine and its esters excreted in the urine of a patient presenting with a severe dicarboxylic aciduria associated with medium-chain acyl-CoA dehydrogenase (MCAD) deficiency.

$\text{D,L-[Me}_1\text{,N-}^2\text{H}_3\text{]carnitine}$, $\text{D,L-[Ac-}^2\text{H}_3\text{]acetylcarnitine}$, and $\text{D,L-decanoyl[Me}_1\text{,N-}^2\text{H}_3\text{]carnitine}$ are added as internal standards, and the sample is prepared as the tri-deuteriomethyl ester for FAB analysis. Esterification of the carnitine carboxylate function with perdeuterio-methanol removes the zwitterionic character of carnitine and its esters, and leaves them with a full positive charge.

Figure 6 Selected-ion monitoring analysis of a urine sample from a patient with the inherited form of tyrosinaemia. Succinyl-acetone, which is distinctly elevated here, is produced from fumarylacetoacetic acid and is measured as an indication of fumarylacetoacetate hydrolase inactivity, the precipitating cause of this form of tyrosinaemia. The ions monitored are the $[M-CH_3]^+$ fragments of the TMS derivatives of the internal standard 2-methoxybenzoic acid (m/z 209.1) and the two positional isomers of the oxime derivative of succinylacetone (m/z 212.1).

It also raises their ion mass by 17 Da to avoid confusion between them and their nonesterified homologues. High-resolution (10 000) spectra confirm the presence of the ions of interest free of interference from unrelated ions of the same nominal masses. Quantitations are then simply a matter of applying the usual calculations associated with a stable-isotope dilution assay. The identity of the annotated peaks is given in **Table 2**, along with the concentrations determined. Large concentrations of acetyl-, propionyl-, nonanoyl-, suberyl- and sebacylcarnitines are found that reflect elevations of the free acids in the urine. As a second illustration of the technique, urine from a patient with propionic acidemia (**Figure 7b**) is shown to have a large concentration of propionylcarnitine (**Table 2**).

ESI has made possible many recent advances in the application of mass spectrometry to diagnostic medicine. Its great sensitivity and applicability to minuscule sample sizes together with its ability to analyse aqueous solutions form the basis of its utility. Because it is also a desorption technique, it is especially useful and sensitive for compounds that incorporate formal charges or chemical groups that are easily ionized.

Trimethylaminuria is an inherited disease related to the inability to convert trimethylamine (TMA) metabolized from dietary sources into trimethylamine *N*-oxide. The result is a disorder that is not clinically acute but has the unpleasant effect of producing a body odour resembling that of rotting fish in those affected. The social consequences of this are severely debilitating. While it is relatively easy to diagnose this disorder, objective means are needed to evaluate the efficacy of treatment protocols. TMA can be quaternized with $[^2H_3]$ methyl iodide and, with ^{15}N -labelled TMA as the internal standard, an ESI method can be used to determine TMA concentrations in urine and blood. **Figure 8a** represents an example of the analysis of a normal urine for TMA. **Figure 8b** is obtained for a similar analysis of another normal urine spiked with 40 ng mL $^{-1}$ of unlabelled TMA.

A known amount of $[^{15}N]$ TMA hydrochloride is added to the urine, the pH of the solution is increased to 12 in an ice bath, an ether extract is made, and an excess of $[^2H_3]$ methyl iodide is added. The resulting ether solution is added to water, which is warmed to drive off the ether and excess methyl iodide, and the remaining

solution is infused by syringe through the ESI probe. Selected-ion monitoring with averaging or short scan modes in multichannel array detection may be used. Calculations usually associated with stable-isotope

dilution analyses are then applied. [$^2\text{H}_3$]Methyl iodide is used as the quaternizing reagent to avoid interference by endogenous tetramethylammonium ions (mass 74 Da) usually present in urine and blood.

Figure 8 Positive ion electrospray spectrum of tetramethylammonium ions produced by quaternization of trimethylamine (TMA) excreted by a patient with trimethylaminuria. When the amine fraction is quaternized with [$^2\text{H}_3$]methyl iodide, endogenous TMA is measured at m/z 77, while the [^{15}N]TMA internal standard is measured at m/z 78. The ion signal at m/z 74 is unlabelled tetramethylammonium produced endogenously, which would interfere with the analysis if unlabelled methyl iodide were used for quaternization.

Figure 9 Negative ion electrospray collision-induced neutral loss of 17 Da (hydroxyl radical) analysis of plasma inorganic sulfate as $\text{H}^{32}\text{SO}_4^-$ (m/z 97) and $\text{H}^{34}\text{SO}_4^-$ (m/z 99). Phosphate, which occurs in plasma in much larger concentrations, also presents an intense ion with mass 97 Da (H_2PO_4^-), but can be distinguished from $\text{H}^{32}\text{SO}_4^-$ and excluded from the analysis as it eliminates 18 Da (water) under similar conditions. Heavy isotopes of hydrogen, oxygen and sulfur included in HSO_4^- in their natural abundances contribute an ion intensity at m/z 99 of about 5% of the intensity at m/z 97. Here the analysis shows that approximately 12% of the sulfate in the sample is derived from an oral load of ^{32}S -labelled sulfate.

A second use of ESI is in the measurement of inorganic sulfate in blood and urine. Sulfate is extruded actively from cells and resides virtually exclusively in the extracellular fluid compartment. Sulfur has four stable isotopes, ^{32}S , ^{33}S , ^{34}S and ^{36}S (95.02%, 0.75%, 4.21% and 0.02%, respectively, although these values may vary somewhat with the nature of the source), and as sulfate it is an end-metabolite of sulfur-containing amino acids and other physiologically significant organosulfur compounds. Sulfate does not respond well in positive-ion FAB or ESI, but in negative-ion ESI the ion HSO_4^- is desorbed very efficiently from aqueous solutions. A stable-isotope dilution assay for sulfate based upon this fact uses highly enriched sodium [^{34}S]sulfate as the internal standard that is added to the biological fluid. The

ratio of the $\text{H}^{32}\text{SO}_4^-$ analyte and $\text{H}^{34}\text{SO}_4^-$ reference ions could then be measured directly at m/z 97 and 99 if phosphate were not also present. H_2PO_4^- also has mass 97 Da, and is present in concentrations much larger than that of sulfate. Collision-induced dissociation of HSO_4^- yields $\text{SO}_3^{\bullet-}$ (80 Da) while H_2PO_4^- yields PO_3^- (79 Da), which distinguishes them in the tandem mass spectrometer. It is then a simple matter to measure the relative abundances of $\text{H}^{32}\text{SO}_4^-$ and $\text{H}^{34}\text{SO}_4^-$ by neutral loss of an OH radical (17 Da), producing ions at m/z 80 and 82, respectively, as H_2PO_4^- dissociates exclusively with the loss of water (18 Da) and does not interfere with the sulfate measurement. An adaptation of this technique can be used to monitor sulfate produced from ^{34}S -containing amino acids in suspected errors of

their catabolism. Radioactively-labelled sulfur-containing substrates have the drawback that ^{35}S (the longest-lived radioisotope) has a half-life of only 87 days, and they must be prepared shortly before each use. ^{34}S sulfate may also be used in tracer studies to follow the excretion of label in the urine following an oral dose of the labelled sulfate. These experiments are usually conducted with radioactive ^{35}S sulfate for the purpose of determining a patient's extracellular fluid volume. An example of this last use is presented in **Figure 9**.

While this article presents and concentrates on examples of the common and routine use of mass spectrometry in the diagnosis of metabolic disease, many other applications are important in the identification and quantitation of metabolites in other areas of clinical medicine.

Traditionally a technique associated with astronomy and organic chemistry, IR spectroscopy has emerged as a powerful technique for the analysis and classification of human tissues and fluids. Such an application is possible because of the sensitivity of IR spectroscopy to changes in tissue biochemistry. In general, IR spectroscopy is sensitive to the structure and concentration of the macromolecules (nucleic acids, proteins, lipids) present in cells and tissues and relatively insensitive to low molecular mass metabolites (such as glucose, lactate and individual amino acids). Disease states that affect tissue ultra-structure are therefore potential targets for IR spectroscopic analysis. For example, cancer is often associated with the appearance of gross nuclear abnormalities, such as the presence of multiple nuclei in cells. As nucleic acids provide some of the most characteristic IR absorptions in biological materials, the changes in DNA associated with cancer result in changes to the spectral signature of malignant cells, and these changes are diagnostic. Changes in absorptions from other macromolecules have been reported to be diagnostic for a wide range of disorders affecting a variety of tissues.

A major advantage of IR spectroscopy is that a single instrument can in principle be used to characterize tissues affected by a wide range of disorders without the need for major reconfigurations of the instrument or the addition of probes (such as stains or other contrast-enhancing reagents) to the sample. In addition, valuable information concerning the molecular nature of the disease process is obtained. A general overview of available sampling methodologies and data analysis techniques will be presented, followed by illustrative examples.

Methodological Aspects

General Comments

Infrared absorption bands from biological materials are generally broad, largely owing to the presence of a heterogeneous population of chromophores. This heterogeneity has two sources. Firstly, functional groups are typically found in a variety of environments (e.g. polar/nonpolar, hydrogen-bonded/non-hydrogen-bonded), giving rise to slightly different but overlapping absorption profiles. Secondly, the complex biochemical nature of tissues, cells and biological fluids means that in many

spectral regions overlapping absorptions from different functional groups are found (e.g. phosphate bands from nucleic acids overlap with collagen bands).

From a methodological viewpoint, this means that high-resolution measurements are not required. Typically, a spectral resolution of 2 or 4 cm^{-1} is sufficient. From an interpretational viewpoint, the presence of such broad absorption bands often means that application of band-narrowing techniques such as Fourier self-deconvolution or derivation is required before information can be reliably extracted from spectra. Application of second-derivative methods has the additional advantage that variations in baseline slope and offset are eliminated. While reducing the width of broad overlapping absorption bands, these techniques also disproportionately enhance the weak but narrow water vapour bands in the 1500–1800 cm^{-1} region, leading to many erroneous assignments in the literature. It is therefore essential that the spectrometer and any sampling accessories be well purged.

Sampling Methods

A wide variety of techniques exists for obtaining spectra from tissues and fluids; the simplest of these are transmission methods. For biological fluids, small volumes (typically 5–10 μL) of sample are placed between a pair of CaF_2 or BaF_2 windows. In the mid-IR the pathlength must be limited to 10 μm or less owing to the presence of intense absorptions from water. Even under these circumstances, absorptions from water dominate the spectrum, and identification of dissolved/suspended materials is difficult. Subtraction of a water spectrum is possible, but it should be borne in mind that the structure of water is altered by dissolved solutes. This alters the spectrum of water, such that water in biological fluids gives rise to spectra that are subtly different from that of pure water. Problems associated with water can be removed by drying the sample to form a thin film. Drying of samples may result in the loss of volatile components from biological fluids, and also results in loss of information relating to hydration of materials. An alternative approach that minimizes sample preparation and prevents loss of information is to acquire spectra in the near-IR spectral region. The absorption bands due to combination and overtone vibrations seen in the near-IR spectral region are significantly reduced in intensity compared to those of the

fundamental vibrations. In practice, this means that longer pathlengths may be utilized before water absorptions become a severe problem. However, it should be remembered that only overtones and combinations of X–H vibrations (X=N, C, O) show significant absorption intensity, reducing the information content of the near-IR spectral region.

For tissue samples, transmission measurements are made in essentially the same way. Samples may be either small pieces of tissue (1 mm³) dissected from a larger sample or microtomed thin sections. In either case, the sample is compressed between calcium fluoride windows. For some tissues (e.g. skin, muscle) such an approach is not possible owing to the high mechanical strength of the sample. For such tissues, specialized sampling techniques and accessories are recommended, such as the attenuated total reflection (ATR) measurements using a ‘split pea’ accessory. Using this approach, tissue is compressed with a reproducible force against a small hemispherical ATR element and spectra are acquired.

A major drawback of these approaches is that the physical integrity of the tissue is destroyed, preventing subsequent histological analysis. The investigator is therefore often uncertain of the exact nature of the sample being studied. This problem may be avoided with the use of an IR microscope. Using this technique, IR light is focused onto a small region of microtomed tissue and a spectrum is acquired. Spectra are sequentially acquired from the entire surface of the tissue by raster scanning with a computer-controlled stage. In this way a complete spectroscopic picture of the tissue section can be obtained with a high spatial resolution. The sample can then be stained and analysed by standard histological methods. This allows a direct correlation between spectra and sample histology, which aids in spectral interpretation.

Analysis of Preserved Samples

In all studies involving biological materials, questions arise of sample degradation over time. With cells and tissues, it is possible to prevent this degradation by fixation with preservatives such as 70% ethanol or formalin. However, these fixatives exhibit strong IR absorptions and are thus a source of potential artefacts. Furthermore, these fixatives preserve tissue by inactivation of degradative enzymes, which may also introduce artefacts into spectra if this inactivation is reflected in changes in protein conformation. Suspension of cultured tumour cells in 70% ethanol significantly alters the absorptions arising from cellular proteins compared to suspension in isotonic saline. Most noticeably, the observation of two protein absorption bands at 1625 and 1680 cm⁻¹ is highly indicative of the formation of aggregates of protein molecules stabilized by intermolecular hydrogen bonding. This is generally associated with large-scale protein

denaturation. The intensity of these absorptions is time dependent, increasing with prolonged suspension in the alcohol, owing to continued penetration of the alcohol into the cells. Fixation with ethanol also reduces the intensity of the ester C=O stretching vibration, suggesting a decreased lipid content in ethanol-fixed cells. This reduction in lipid content reflects solubilization of membrane lipids by ethanol.

Spectra of cells dried from formalin do not show the characteristic absorption associated with protein aggregates, indicating that formalin fixation does not induce protein denaturation. However, drying from formalin does result in the appearance of a series of sharp absorptions between 1000 and 1500 cm⁻¹. These narrow absorption bands arise from formaldehyde that is retained in salt crystals in the film. These distinctive absorptions are not present if the cell suspension is washed with isotonic saline before drying. Formalin should therefore be the fixative of choice for the vibrational spectroscopist, and cells and tissues should be rinsed with isotonic saline before spectral acquisition.

Spectral Interpretation and Data Analysis Methods

The Group Frequency Approach

IR spectra have traditionally been interpreted by assigning absorptions that fall in particular frequency ranges to specific functional groups within molecules, in what is termed the functional group approach to spectral interpretation. Thus, absorption bands in the range 2800–3050 cm⁻¹ are attributed to carbon–hydrogen stretching vibrations of ethylene, methylene and methyl groups, while absorptions at 1700–1750 and 1600–1700 cm⁻¹ are attributed to stretching vibrations of ester and amide C=O groups, respectively. A brief summary of the assignment of major absorptions in biological systems is presented in **Table 1**. Using such classical assignments, the biochemical and histological properties of tissues and cells may be inferred.

Functional Group Mapping

In an extension of the functional group approach to spectral analysis, data acquired by mapping tissues using an IR microscope may be analysed using an approach termed functional group mapping. The principle behind functional group mapping is illustrated in **Figure 1**. A grid first defines the area of the sample to be analysed. A spectrum is then sequentially acquired from each pixel in the grid, and the intensity or peak frequency of an absorption band arising from a functional group of interest is calculated for each spectrum. The intensity or frequency of the absorption band is then plotted as a function of position within the grid to produce a map of

Table 1 Frequencies of biologically important IR absorptions. All absorptions cover a range of frequencies, and only representative frequencies are given here

Frequency (cm^{-1})	Assignment
3500	OH stretch; water, carbohydrates
3290	Amide A (N–H stretch): proteins
3050	Amide B (N–H bend first overtone): proteins
3010	Olefinic =CH stretch: lipids, cholesterol esters
2955	CH ₃ asymmetric stretch: lipids, proteins, carbohydrates, nucleic acids
2925	CH ₂ asymmetric stretch: lipids, proteins, carbohydrates, nucleic acids
2875	CH ₃ symmetric stretch: lipids, proteins, carbohydrates, nucleic acids
2855	CH ₂ symmetric stretch: lipids, proteins, carbohydrates, nucleic acids
2600	S–H stretch: proteins
2340	Solution phase and enclathrated CO ₂
2058	SCN stretch: thiocyanate
1740	Ester C=O stretch: lipids, cholesterol esters
1655	Amide I (amide C=O stretch): proteins, α -helices
1635	Amide I (amide C=O stretch): proteins, β -sheet
1545	Amide II (amide N–H bend): proteins
1515	'Breathing' vibration of tyrosine ring (C–C/C=C stretching)
1467	CH ₂ bend: lipids, proteins, cholesterol esters
1455	CH ₃ asymmetric bend: lipids, proteins, cholesterol esters
1400	COO [−] symmetric stretch: amino acid side chains, fatty acids
1380	CH ₃ symmetric bend: lipids, proteins, cholesterol esters
1280	Amide III (C–N stretch) of collagen
1240	PO ₂ [−] asymmetric stretch: phospholipids, nucleic acids; amide III (C–N stretch) of collagen
1204	Amide III (C–N stretch) of collagen
1170	CO–O–C asymmetric stretch: phospholipids, cholesterol esters
1150	C–O stretch, carbohydrates (glycogen)
1080	PO ₂ [−] symmetric stretch: lipids, nucleic acids. C–O stretch, glycoproteins
1060	CO–O–C symmetric stretch: phospholipids, cholesterol esters
1035	C–O stretch, glycoproteins, carbohydrates

intensity or frequency distribution. In essence, therefore, this functional group mapping produces an image of the distribution of materials throughout the sample. For complex samples such as tissue sections, the distribution of important constituents such as collagen, proteins, acylglycerides and nucleic acids throughout the sample can be measured. These 'chemical images' can then be directly compared with the stained tissue to allow correlation of spectral and histological features.

Statistical and Multivariate Analysis

Spectroscopic differences between tissues or cell types are often subtle, leading to difficulties in determining the significance of any observed differences. This is illustrated

by a comparison of baseline-corrected mean spectra of cultured melanoma, lung adenocarcinoma and breast tumour cells (**Figure 2**). Spectra of the three cell types appear essentially identical, dominated by absorptions from proteins and nucleic acids. However, subtle differences are apparent throughout the spectra, including the region exhibiting absorptions from nucleic acid phosphate vibrations. Given the subtle nature of these spectral differences, the question arises as to the significance of the differences. Obviously, significance must be assessed using statistical techniques. The simplest way to assess whether significant differences exist between sets of spectra is to perform Student's *t*-tests. The results of *t*-tests performed to compare the second-derivative spectra of the three groups of cells at each wavelength between 1000 and 1750 cm^{-1} are shown in **Figure 3**. For each comparison, the probability that differences between spectra at each wavenumber arose by chance is plotted. Thus, significant differences exist between spectra of breast and lung adenocarcinoma cells at a number of wavelengths. Similarly, significant differences exist between breast and melanoma cells and between melanoma cells and lung adenocarcinoma cells throughout the spectrum.

Such an analysis allows important conclusions to be drawn. For example, the greatest number of significant differences are found between spectra of breast tumour cells and melanoma cells, indicating that these two cell lines have the most different cellular biochemistry. In contrast, lung adenocarcinoma cells and melanoma cells appear to be the most similar as indicated by the high proportion of wavelengths at which no significant difference is found between spectra. Significant differences are found between all cell lines in the region of the nucleic acid phosphate vibrations, implying that the structure of the DNA in the three cell lines is different.

Analysis of differences between spectra by application of Student's *t*-test directly complements the traditional group frequency approach to spectral interpretation. Unfortunately, spectral regions in which significant differences exist between cell or tissue types are not necessarily the regions that allow optimal classification of spectra into groups based upon cell or tissue type. For example, significant differences exist between spectra of breast and melanoma cells between 1220 and 1240 cm^{-1} . However, lung adenocarcinoma cells also differ significantly from breast cells in this region. Thus, the only conclusion that can be drawn is that these cells are not breast cells. More definitive identification requires a comparison of a number of spectral regions, or even the entire spectral range.

Such definitive classification may be achieved with the aid of multivariate pattern recognition techniques such as hierarchical clustering, linear discriminant analysis (LDA) and artificial neural network analysis. Hierarchical clustering techniques compare sets of data (e.g. individually acquired spectra or spectra acquired by mapping

Figure 1 Pictorial description of the procedure for functional group mapping.

Figure 2 Infrared spectra of cultured human breast and lung tumour cells and murine melanoma tumour cells.

of tissue) and group the data according to some measure of similarity. For mapping data, the application of cluster analysis methods allows the identification of regions of the tissue that give rise to similar spectra and, by inference, have similar biochemistry. The advantage of such methods is that they perform a direct comparison of the spectral data (i.e. they are unsupervised, requiring no input from the investigator), and do not require assignment of spectral features.

More powerful multivariate methods such as LDA make use of the fact that the investigator is often in possession of class assignments (e.g. cell type). In such

cases, so-called supervised methods such as LDA can be trained to detect patterns in the spectral data unique to each class. Unknown spectra can then be analysed using the trained algorithm to determine the appropriate class assignment based upon the spectral patterns present.

Applications of IR Spectroscopy in Medicine: Examples

With due regard to sampling, measurement and data analysis considerations, the application of IR

Figure 3 Results of Student's *t*-tests performed to assess the significance of differences between spectra of cultured human breast and lung tumour cells and murine melanoma cells.

spectroscopy to tissue, fluids and cells yields a remarkable amount of information. This information may relate to the concentration of particular analytes in biological fluids, the distribution of analytes within tissue, or the nature of biochemical changes associated with the disease process. In addition, information concerning metabolic processes in tissues and cells may be obtained. Examples will be presented to illustrate the general applicability of the technique.

Analyte Determination

A major advantage of IR spectroscopy is that an IR spectrum is the summation of the spectra of all of the IR-active species present in the sample, weighted with respect to concentration. This means that the concentration of each of the major IR active analytes in a biological fluid can be predicted from a single IR spectrum. In practice this is achieved using such techniques as partial least squares (PLS) regression analysis, in which IR spectra are regressed against laboratory values for the concentration of analytes of interest to calibrate the method. This calibrated regression method can then be used to predict the concentration of the analytes from the spectrum of a fluid of unknown composition. Application of PLS methods to IR spectra can result in predictive accuracy as good as that of standard laboratory tests for many clinically relevant analytes such as glucose, urea, triglycerides and total protein (**Figure 4**).

Monitoring of Metabolism

PLS techniques are required to decode the concentration information for most analytes present in biological fluids owing to the high degree of overlap between absorptions from most analytes. However, carbon dioxide exhibits a highly characteristic absorption in aqueous solution in a spectral region generally devoid of other absorptions (2340 cm^{-1}). This makes it relatively trivial to monitor CO_2 concentration. As CO_2 is a major by-product of cellular respiration, monitoring the intensity of this absorption in living systems should provide an indication of the rate of cellular metabolism. Obviously this cannot be done *in vivo* with current technology. However, monitoring the rate of respiration within suspensions of cells is possible. **Figure 5** shows the intensity of the absorption at 2340 cm^{-1} as a function of time for a suspension of yeast cells incubated with glucose. An increase in intensity with time as the glucose is metabolized is readily apparent. A second, weaker absorption is apparent at 2275 cm^{-1} , attributed to the naturally occurring ^{13}C isotope of CO_2 . The increase in intensity of this second absorption with time in the presence of ^{13}C -labelled glucose confirms that cellular respiration is indeed responsible for the increase in the intensity of the absorptions at 2275 and 2340 cm^{-1} with time. More importantly, the ability to detect metabolically produced $^{12}\text{CO}_2$ and $^{13}\text{CO}_2$ should allow IR spectroscopy to be used as a method for the elucidation of metabolic pathways in living cells using specifically labelled materials.

Figure 4 Concentration of triglycerides, urea, glucose and protein predicted by partial least-squares analysis of infrared spectra of serum plotted against reference values.

Grading of Breast Tumours

As discussed above, differences between spectra of cultured tumour cell lines may be subtle and difficult to discriminate from normal biological variability. Searching for diagnostic features in this relatively simple system may be compared to searching for the proverbial needle in a haystack, and multivariate pattern recognition methods are required. With this in mind, the task of identifying spectroscopic differences between sections of intact tissue becomes a daunting one. Not only must one find the subtle spectroscopic differences that exist between normal and diseased cells, but this information must now be extracted from the large signal arising from the matrix in which the cells sit. As an additional problem, the signal arising from the matrix may itself vary, either as a function of the disease or independently of the disease. The problem now becomes one of finding a needle in a field of haystacks.

The contribution of the extracellular matrix to spectra of breast tissue is shown in **Figure 6**. The spectra of low-grade breast tumours are vastly different from the spectra of cultured breast tumour cells. Breast tissue is composed predominantly of epithelial cells, connective tissue and

adipose tissue. If we assume that cultured breast tumour cells and *in situ* breast tumour cells give rise to essentially similar spectra, then the differences seen between the spectra of tumours and cultured cells must reflect the presence of adipose and connective tissues. More specifically, a series of absorptions may be attributed to collagen and triglycerides. This example serves to illustrate not only the extent to which the extracellular matrix influences spectra, but also how spectroscopic studies of cultured cells can be used to identify such matrix effects.

To overcome the problem of matrix interferences and allow grading of tumours, spectra must be analysed by multivariate pattern recognition methods. Much of the spectral data is not related to changes associated with disease progression but results from normal spatial variations in breast histology. This information is therefore redundant, and only serves to increase computation time. Application of a genetic algorithm can be used to determine which regions of the spectrum carry the most useful diagnostic information. These regions can then be used as input for a pattern recognition strategy. Using this approach, tumours can be correctly classified as low, intermediate or high grade with an accuracy approaching 90%.

Figure 5 The intensity of the ¹²CO₂ and ¹³CO₂ absorption bands as a function of time in suspensions of yeast incubated with (a) ¹²C and (b) ¹³C labelled glucose.

Figure 6 Infrared spectra of cultured human breast tumour cells and two low-grade human breast tumours. Absorptions marked (a) and (c) arise from adipose tissue and collagen, respectively.

Figure 7 Functional group maps of a thin section of a subcutaneous tumour from a nude mouse showing adipose tissue and collagen distribution.

Microscopic Studies of Tumours

The problem of tissue homogeneity can also be addressed using IR microscopy and functional group imaging. Functional group maps showing collagen and adipose tissue distribution in a thin section of a subcutaneous murine tumour are shown in **Figure 7**. These maps are generated by plotting the intensity of characteristic absorptions from collagen and adipose tissue at each point within the map. The flat regions surrounding the tissue periphery correspond to the calcium fluoride substrate on which the tissue is supported. A low lipid content and a high collagen content characterize the periphery of the tissue, suggesting that this region of tissue is the epidermis and dermis. Underlying the epidermis/dermis, a large deposit of adipose tissue can be identified. A discrete band of collagen can then be seen forming a boundary layer around a central mass. This central mass is rich in protein and nucleic acids (as determined from functional group maps of the amide I and phosphate absorptions) but is low in collagen, identifying it as the main body of the tumour. The collagen found around the periphery of the tumour can therefore be recognized as part of a capsule surrounding the tumour. Functional group mapping thus allows identification of discrete histological structures within tissues.

In Vivo Spectroscopy and Imaging

IR spectroscopy can be used to probe tissue biochemistry *in vivo*, using fibre optic accessories to bring the IR light to the patient. Such *in vivo* studies are performed almost exclusively in the near-IR region of the spectrum, owing to the enhanced penetration of near-IR light into tissues.

However, applications have been limited by the low information content of near-IR spectra. To date, most near-IR spectroscopic studies have focused on two main areas: blood glucose analysis and haemodynamic monitoring.

Attempts to develop methods for the noninvasive determination of blood glucose have met with little success, despite more than three decades of research. Major problems include (i) the complex nature of skin; (ii) variations in the thickness and composition of skin within and between individuals and the consequent difficulties with variations in light scattering; (iii) the relatively low concentration of glucose in body fluids; (iv) the low intensity of the glucose signal in the near-IR; and (v) overlap of glucose absorption bands with absorption bands from water and other tissue components. Subtle effects such as changes in skin temperature and hydration further complicate the problem.

Haemodynamic monitoring has proved more successful. Haemodynamic monitoring using near-IR spectroscopy is possible owing to the occurrence of electronic transitions in the metal ions of haemoglobin and cytochrome species that are stimulated by absorption of near-IR light. Oxyhaemoglobin, deoxyhaemoglobin, oxidized cytochrome *aa₃* and reduced cytochrome *aa₃* exhibit absorptions in the near-IR region of the spectrum that are readily observed. Analysis of the relative intensities of these absorptions can therefore be used to assess tissue oxygenation and oxygen utilization within tissues. In addition, by combining an analysis of the haemoglobin and cytochrome absorptions with an analysis of tissue water absorptions, it is possible to extract information relating to haematocrit, tissue blood volume and blood flow.

Figure 8 Noninvasive near-infrared imaging of the human forearm using a 512×512 array of CCD detectors. Visible image (upper panel) and results of cluster analysis on each pixel for the deoxyhaemoglobin absorption at 760 nm (lower panel). Areas with similar shading have similar deoxyhaemoglobin levels.

The majority of such studies have been conducted using fibre optic-based systems. Spectra can be obtained from a small area of tissue by keeping to a minimum the distance between the fibre optic cables that bring the light to the tissue and those that return the light to the spectrometer. This approach provides information on a highly localized area but does not provide gross haemodynamic information. Alternatively, the distance between the fibres may be increased and a large volume of tissue can then be probed. This approach provides

information relating to the average haemodynamic parameters of the large volume of tissue. However, this approach does not allow localized haemodynamic information to be obtained. Recently, the availability of high-sensitivity charge-coupled-device (CCD) cameras that operate in the near-IR spectral region has been exploited to generate images that provide information concerning the haemodynamic parameters of large areas of tissue with a high spatial resolution. For example, an area of skin $10 \text{ cm} \times 10 \text{ cm}$ can easily be imaged using a CCD camera with a 512×512 array detector. Spectra are obtained from each detector in the array, and each spectrum then corresponds to a region of the tissue approximately $200 \mu\text{m} \times 200 \mu\text{m}$. Haemodynamic parameters can be obtained from each spectrum, and these parameters can be used to produce an image. Thus, the global haemodynamic parameters of the $10 \text{ cm} \times 10 \text{ cm}$ area of skin can be assessed, but information can also be obtained related to haemodynamic parameters with a spatial resolution limited only by diffraction.

The large amount of information generated in this manner (250 000 spectra) is ideally suited to multivariate analytical methods such as cluster analysis. Combining near-IR imaging and multivariate analysis allows one to determine nonsubjectively regions of tissue having similar haemodynamic properties (**Figure 8**). The applications of such techniques in areas such as wound healing are obvious.

Introduction

Molecular motions in biomembranes are highly anisotropic. Since essentially all aspects of NMR spectroscopy are affected by molecular motions, the details of these motions strongly influence the spectroscopic approaches that can be applied to membrane samples. Although the motions of individual molecules or molecular groups may be very rapid (the molecular correlation time, τ_c , is in the ns range for lipid hydrocarbon chains and amino acid side chains of proteins), the overall tumbling of the lipid and polypeptide molecules in membrane bilayers is very slow and can be in the ms or s range. For this reason, conventional solution-state NMR, which relies on rapid overall molecular reorientation to narrow the resonance lines, has found little success in membrane research; even a lipid molecule with a relative molecular mass (M_r) of ~ 1000 or a small peptide ($M_r \sim 3000$) has, when in membrane bilayers, by solution-state NMR criteria a tumbling rate equivalent to a very large ($M_r \gg 30$ kDa) macromolecule in free solution. Only by sonicating the sample to produce small (diameter 20–50 nm) bilayer vesicles can conventional solution-state NMR methods be used. However, not only are there very serious concerns about the status of the lipids and polypeptides embedded in highly distorted lipid bilayers, but also those portions of proteins embedded in the bilayers may still reorient too slowly to yield resolvable resonances. Solution-state NMR spectroscopy has been applied to peptides and proteins in organic solvents, detergent micelles and bicelles (**Figure 1**), and structures have been determined in these model membrane environments. While micelles certainly provide a more relevant environment for membrane proteins than do mixtures of organic solvents, fully hydrated lipid bilayers remain the definitive environment for structural and functional studies of membrane proteins.

As an alternative approach to solution-state NMR methods, which are ineffective with lipid bilayer samples, solid-state NMR methods have been refined sufficiently to permit structural details to be obtained for membrane-embedded peptides and proteins. This usually requires isotopic enrichment, either through chemical synthesis or through biosynthetic incorporation in expressed peptides and proteins. In the absence of routine X-ray

Figure 1 Representation of the types of sample preparations used for studying membrane lipids and proteins. Micelles and bicelles are usually small (diameters ~ 20 – 50 nm) structures and bilayers can be sonicated into small (20–50 nm diameter) vesicles, or produced as extended (diameters $\gg 100$ nm) multi-bilayered or single bilayered closed or open structures, depending upon the method of preparation. Natural membranes are usually as large bilayer fragments or closed structures containing a complex and heterogeneous mixture of lipids and proteins and possibly carbohydrates.

crystallographic structural studies for these molecules, solid-state NMR spectroscopy has the potential to be a powerful and unique approach to determining the structures and describing the dynamics and functions of membranes and membrane-bound proteins. In addition, solid-state NMR spectroscopy has been widely used to describe lipid structure, dynamics and phase properties. Thus, solid-state NMR experiments can be applied to both the polypeptide and lipid components of membrane bilayers, without the need to disrupt the sample through sonication or the addition of organic solvents or detergents.

Nuclei Used in Membrane Studies

With the exception of J -couplings, the major magnetic interactions (chemical shift, dipolar and quadrupolar couplings) for the nuclei exploited in biological NMR can be averaged with respect to the applied fields ($B_0 \sim$ MHz and $B_1 \sim$ kHz) by isotropic molecular motion of small molecules (**Table 1**). However, for biomembranes, any of these interactions may yield resonances with very broad lines and dominate the spectra, masking the resolution required for high resolution studies. Where these

interactions can be exploited, their anisotropy (usually chemical shift, dipolar or quadrupolar) can give molecular orientational information from static samples, either oriented or as random dispersions (see below). Alternatively, magic angle spinning (MAS) of the sample can be used at spinning speeds (ω_r) which are either fast enough to average the interaction completely ($\omega_r \gg \sigma, D, Q$) to give high resolution-like solid-state NMR spectra, or may be moderated either to recouple a dipolar interaction, such as in rotational resonance or REDOR, or to provide orientationally dependent spinning spectral side-bands for nuclei which display chemical shift anisotropy (e.g. ^{31}P , ^{15}N).

Naturally occurring ^{13}C (natural abundance and with selective enrichment) and ^{31}P nuclei have been extensively exploited in membrane NMR studies (Table 2). However, replacement of ^1H by ^2H or ^{19}F , and ^{14}N by ^{15}N , has also found widespread application, although to date ^{17}O has not found application in these systems. Typical spectra for the more commonly exploited nuclei for lipids in bilayers are shown in Figure 2.

The need to average the strong dipolar coupling (~ 100 kHz) for ^1H to obtain high resolution spectra has excluded widespread observation of this nucleus in membranes. Extensive protein deuteration, to leave a minor ^1H density at a site of interest for observation in micellar suspensions, has been achieved. The realization that reorientation around the long molecular axis rotation of lipids and proteins in membrane bilayers in the liquid crystalline phase is sufficiently fast (at about 10^9 Hz for lipids and 10^6 Hz for proteins with radius ≤ 4 nm in fluid membranes) to average even homonuclear ^1H dipolar couplings, has opened a new avenue for membrane studies for most observable nuclei, including ^1H without the need for isotopic replacements. In addition, it is possible to perform magic angle oriented sample spinning (MAOSS) experiments to reap the benefits of both sample orientation and magic angle sample spinning in this situation.

Table 1 Comparison of the strengths of the magnetic interactions in NMR and the ways in which they can be averaged to yield molecular information for lipids, peptides and proteins in membranes in liquid state and solid state approaches

Interaction	Liquids (Hz)	Solids (Hz)	Methods
σ	$10\text{--}10^4$	$10\text{--}10^4$	MAS
J	10^2	10^2	Decoupling
D	0	10^4	Decoupling, MAS
Q	0	$10^5\text{--}10^6$	MAS

Nature of the Sample

Depending upon the kind of information desired, membrane bilayer samples can be prepared either oriented with respect to the applied field, or as random dispersions. For most studies, full hydration (> 30 wt% of water) is desired, especially for protein studies where denaturation may occur and biological function be lost without sufficient amounts of water present.

Oriented Membranes

Both natural and synthetic membranes can be effectively oriented and studied using NMR. In general, reducing the hydration level of biomembranes supported and oriented on a substratum (glass or mica plates) improves their orientation, but if less than limiting levels of hydration are used ($\sim < 30$ wt%), alterations may occur in the lipid phase from bilayer to isotropic or hexagonal phases. Fortunately, for all orientational studies of membranes, a good internal check for orientation can be made from the ^{31}P NMR spectrum of the bilayer phospholipids, since the line positions in the spectra recorded at 0° and 90° are separated by 40–50 ppm (Figure 3). The average mosaic spread can then be estimated from the spectral line-width.

Synthetic, model membranes, made from pure lipids, are best oriented on glass plates by drying down an organic solvent (usually $\text{CHCl}_3/\text{MeOH}$) solution of the lipid at $1\text{--}5$ mg mL^{-1} . Overloading the lipids onto a substratum generally produces less good orientation, and some lipids (notably zwitterionic ones such as phosphatidylcholines and phosphatidylethanolamines, both of which are major natural membrane components) orient better than others (anionic ones in particular), with cholesterol aiding orientation. Removal of solvent under high vacuum ($< 10^{-4}$ torr; 1 torr = 133.322 Pa) is followed by hydration, either by dropping buffer or water onto the film, or by incubating in a controlled atmosphere. It is also possible to orient hydrated random dispersions of lipids and proteins by applying pressure to the glass plates. In contrast, natural membranes are most readily oriented on glass plates using the isopotential spin dry ultracentrifugation (ISDU) method which involves centrifugation of a membrane dispersion followed by partial dehydration.

Membrane proteins prepared by solid-phase peptide synthesis or expression in bacteria can be reconstituted into lipids from detergents or organic solvents. The samples are placed on glass plates whose size and shape are determined by the radiofrequency coil with flat or square geometries for optimal filling factors in stationary experiments, or by the rotor for magic angle oriented sample spinning (MAOSS) NMR experiments. While most stationary experiments utilize samples arranged so

Table 2 Properties, advantages and disadvantages of the commonly used nuclei in studies of membranes

Nucleus	Relative sensitivity	Measured parameters	Advantages	Disadvantages	Common applications
^1H	1000	High resolution spectra Chemical shift, T_1 , T_2	High sensitivity Natural abundance	Reasonable spectra with small vesicles, micelles, high speed MAS or MAS of oriented bilayers Several relaxation mechanisms Overlapping resonances Need for selective deuteration Low sensitivity	Dynamic properties Lipid diffusion
^2H	9	Powder spectra Quadrupole splitting T_1 , T_2	Direct determination of order parameters and bond vectors Measurable in cells and dispersed lipids T_1 dominated by fast (ns) motions T_2 dominated by slow (μs –ms) motions Low natural abundance		Ordering properties of phospholipids Dynamic properties of phospholipids
^{13}C	16	High resolution spectra Chemical shift T_1 Dipolar couplings	Natural abundance T_1 dominated by one mechanism	Need MAS NMR to resolve spectra Without selective enrichment, overlapping resonances	Dynamic properties of phospholipids Lipid asymmetry Ligand–protein interactions Distance measurements Quantitation of lipid composition
^{31}P	66	High resolution and powder spectra Chemical shift σ T_1 NOE	Natural abundance Chemical shift anisotropy is sensitive to headgroup environment and phase properties of the bulk lipids Measurable in cells and in dispersed lipids	Individual lipid classes cannot be resolved in mixed bilayer systems unless sonicated or MAS NMR is used	Lipid asymmetry Phase properties
^{15}N	1.04	High resolution spectra Chemical shift σ T_1 , T_2	Cost of labelling is low Can be incorporated in growth media Chemical shift sensitive to conformation	Low natural abundance, means of labelling required Overlapping resonance	Labelling of proteins and peptides Structural and dynamic studies
^{19}F	830	High resolution and powder spectra Chemical shift σ T_1	Chemical shift is sensitive to positional isomers Order parameters can be obtained High sensitivity Measurable in cells and in dispersed lipids	Need for selective fluorination Two factors contribute to the line shape, complicating the analysis High power proton decoupling is difficult May induce chemical perturbation compared to ^1H	Ordering properties of phospholipids

σ , Chemical shift anisotropy; T_1 , spin–lattice relaxation time; T_2 , spin–spin relaxation time; NOE, nuclear Overhauser effect; MAS, magic angle spinning.

Figure 2 Typical spectra for various nuclei exploited in studies of lipids in bilayers. ^1H , a spectrum of phosphatidylcholine multi-bilayers, recorded under magic angle oriented sample spinning (MAOSS) conditions to give rise to narrow (~ 9 Hz) spectral lines; ^{13}C , proton-decoupled spectrum of sonicated, small (diameters < 50 nm) phospholipid vesicles; ^2H , a typical deuterium NMR spherically averaged powder pattern for phospholipid bilayers deuterated in the choline head group, showing the way in which the quadrupole splitting ($\Delta\nu_Q$) is determined; ^{19}F , spectrum of sonicated vesicles of lipids specifically ^{19}F -labelled in the 12' position of both acyl chains; ^{31}P , a static, spherically averaged powder pattern from mixed, cardiolipin, phosphatidylcholine and phosphatidylethanolamine bilayers showing the lack of spectral resolution of the three lipid types (upper spectrum), and under MAS conditions to resolve the three individual phospholipids (lower spectrum).

Figure 3 Orientational dependence of the ^{31}P NMR spectra (at 36.4 MHz) of planar multi-bilayers of phosphatidylcholine, where δ is the angle of the applied field with respect to the membrane normal. $T = 77^\circ\text{C}$. Reproduced with permission from Seelig J and Gally HU (1976) Investigation of phosphatidylethanolamine bilayers by deuterium and phosphorus-31 nuclear magnetic resonance. *Biochemistry* 15: 5199–5204.

that the bilayer normal is perpendicular to the direction of the applied magnetic field, it is possible to perform orientational-dependent studies with the addition of a goniometer, which is usually rotated from the probe base without probe removal from the magnet. For MAOSS NMR experiments, the smallest diameter circular thin glass plates which can be handled are usually 4 mm, but for greater sensitivity, larger (up to 14 mm) rotor probes can be used to accommodate larger plates.

Random Dispersions of Membranes

Extensively sonicated dispersions of pure lipids usually form small single bilayer vesicles. These samples have been used extensively for ^{13}C NMR relaxation studies, which describe the motional properties of the various lipid groups, but have not been widely applied to proteins in membranes.

Natural membrane fragments or vesicles, large (diameter > 50 nm) liposomes, and hydrated unsonicated lipid dispersions are all indistinguishable (because of their slow tumbling) from the NMR perspective. They all give rise to anisotropically broadened spectral envelopes without the application of solid-state NMR techniques. For these systems, a spherically averaged powder pattern is observed which may be narrowed by molecular motion. Magic angle sample spinning (at a rate of ω_r) narrows many of the spectral features, but some potential orientational information content may be lost at high spinning rates ($\omega_r \gg \text{CSA, D or Q}$; **Table 1**) where there are few spinning side bands to analyse.

Experimentally, the amount of sample required is determined by the sensitivity of the nucleus to be observed. Typically, mM of the sample (5–10 mg of lipid; 0.5–1 mg of a small peptide; 1–4 mg of a large protein) in a volume of about 0.7 mL or on 10–50 glass plates may be needed for less sensitive (^2H , ^{15}N) nuclei. For ^1H , ^{19}F , ^{31}P and ^{13}C in MAS NMR, somewhat less material is required. Cross-polarization from the abundant proton magnetization may improve sensitivity, and decoupling (5–10 kHz for ^{31}P , 80–100 kHz for ^1H) is routinely used to improve spectral shape and reduce spectral widths.

Micelles and Bicelles

Micelles (SDS is often used) and bicelles (made of long and short chain phosphatidylcholines) tumble isotropically in solution and can accommodate peptides and proteins (Figure 1) to provide better mimetics for membrane proteins and peptides than organic solvents, which themselves can induce secondary structures in peptides and proteins. Indeed, good protein function and high resolution NMR spectra can be obtained from micellar-protein complexes, with sufficient resolution to permit structural analysis. Bicelles align in the applied field with the membrane normal perpendicular to the applied field, and by doping the system with lanthanides (Tm, Yb, Er or Eu) the orientation can be turned through 90° . Using paramagnetic chelates, direct protein–lanthanide interactions can be abolished leading to better spectral resolution although some hysteresis effects due to molecular reorganization may complicate their use.

Information Content

Macroscopic Structures

Phospholipids can, in aqueous dispersion, form a range of macroscopic structures including bilayers (predominantly for long chain derivatives, C_{12} – C_{24}), hexagonal, cubic and rhombic structures (Figure 4). ^{31}P NMR of static samples is a good diagnostic way of identifying such structures. Spherically averaged powder patterns (with a CSA of ~ 40 – 50 ppm) from bilayers are reversed and reduced in spectral widths (by 0.5) for hexagonal structures because of the added degree of freedom of molecular motion along the hexagonal cylinder. Isotropic spectra arise from small (diameter ≥ 50 nm) vesicles, cubic, rhombic and micellar molecular arrangements, as a result of molecular reorientation of the structure with respect to the applied field which is fast enough to average the frequency-dependent ^{31}P chemical shift anisotropy ($\tau_c < 3$ – 10 kHz ~ 40 – 50 ppm on 200–600 MHz instruments). Similar spectral changes are observed with ^2H NMR for deuterated lipids in similar structures.

Figure 4 Three different types of phospholipid phases and their corresponding ^{31}P NMR spectra. From Cullis PR and Kruijff B (1979) Lipid polymorphism and the functional roles of lipids in biological membranes. *Biochimica et Biophysica Acta* 559: 399–420.

A two-component bilayer and isotropic ^{31}P NMR spectrum from a membrane (usually a natural membrane) has been interpreted in terms of a major bilayer structure encompassing a much smaller ($\leq 5\%$) population of inverted micelles. Although not the only explanation, the interpretation has many functionally attractive features (enhanced permeability, sites of membrane fusion, flip-flop regions, etc.). Such isotropic spectral components are often produced by proteins interacting with the surface of lipid bilayers. The identity of the lipid type, in a mixed lipid membrane, which exists in this isotropic environment, can be determined using MAS ^{31}P NMR methods.

Molecular Structure

Lipid bilayers are two-dimensional, axially symmetric structures with the normal to the plane of the bilayer being a reference axis. Lipids usually rotate quickly ($\tau_r \sim \text{ns}$) around their long axis in fluid bilayers, but peptides and proteins may lack this motion which is determined by the association (controlled oligomerization or irreversible aggregation) behaviour of the various components, as well as the lipid dynamics.

Lipid orientational information

By exploiting the anisotropic properties of the nuclear spin-interactions of ^2H , ^{13}C and ^{15}N (Table 1), placed at specific positions in peptides and ligand, rather precise bond vectors have been determined in oriented membranes.

Deuterium has low natural abundance and a low γ , but the quadrupole coupling can give rise to large splittings in the ^2H NMR spectrum ($\Delta\nu_q(\text{max}) \sim 127 \text{ kHz}$), which is averaged by rotation of a methyl group around a C_3 axis (to $127/3 \sim 40 \text{ kHz}$). This high degree of orientational sensitivity has been exploited to determine the structure of specific residues (valines) involved in dimeric association for the gramicidin ion channel, and the structure of retinal within its binding site of bacteriorhodopsin and rhodopsin. Spectral simulations are necessary, as is some estimate of line broadening due to macroscopic mosaic spread (from ^{31}P spectral widths), but as a general method, the information gained is *ab initio* and, as such, model-independent. Most amino acids are available in a ^2H -labelled form for incorporation into peptides in solid phase synthesis, and a wide range of ^2H -precursors are available for specific labelling of ligands and prosthetic groups.

Peptide and protein orientation

Many results have been obtained with specific, selective and uniform labelling of polypeptide sites with the spin $I=1/2$ nuclei ^{13}C and ^{15}N . These results have included the structure determination of gramicidin in bilayers, the geometrical arrangements of a variety of helical peptides in bilayers, the three-dimensional structures of peptides in bilayers, and the orientations of bound ligands and prosthetic groups. Uniform labelling of proteins with ^{15}N offers many advantages, and, indeed, was first developed for solid-state NMR spectroscopy before being applied to solution-state NMR where it has achieved nearly universal use. The nitrogen sites in the protein backbone are separated by two carbon atoms, leaving only minimal homonuclear ^{15}N dipolar effects, which is the essence of dilute-spin solid-state NMR spectroscopy. Each residue has one amide nitrogen in the backbone (with the exception of proline) and some have distinctive side-chain nitrogen sites. Further, uniform labelling allows the use of expressed proteins, and shifts the burden from sample preparation to spectroscopy, where complete spectral resolution is the essential starting point for structure determination.

Multidimensional solid-state NMR experiments have been shown to yield completely resolved spectra of uniformly ^{15}N labelled proteins in oriented lipid bilayers. In three-dimensional spectra, each amide resonance is characterized by three frequencies (^1H chemical shift, ^{15}N chemical shift and ^1H - ^{15}N heteronuclear dipolar coupling), which provide the source of resolution among the various sites as well as the basic input for structure determination based on orientational constraints. The data shown in **Figure 5** are from a 50-residue protein in oriented lipid bilayers. More importantly, since the polypeptides are immobilized by the lipids on the relevant NMR time-scales, there can be no further

Figure 5 Multidimensional solid-state NMR spectra of uniformly ^{15}N labelled fd coat protein in oriented lipid bilayers. Panel (a) is the complete two-dimensional ^1H - ^{15}N heteronuclear dipolar- ^{15}N chemical shift spectrum. Panels (b) and (c) are spectral planes extracted from a three-dimensional correlation spectrum at specific ^1H chemical shift frequencies. The spectral regions in the planes correspond to the boxed regions of the complete two-dimensional spectrum with which they are aligned. Panel (b) contains resonances with ^1H chemical shift of 11.0 ppm. Panel (c) contains resonances with ^1H chemical shift of 11.6 ppm. The three orientationally dependent frequencies that can be measured for all of the resonances in the three-dimensional data set provide the input for structure determination. The arrow in panel (b) points to the resonance assigned to the amide of Leu 41 in the trans-membrane hydrophobic helix and that in panel (c) to the amide of Leu 14 in the in-plane amphipathic helix.

degradation of line widths or other spectroscopic properties as the size of the polypeptide increases. Although larger proteins will have more complex spectra resulting from the increased number of resonances, there is no fundamental size limitation to solid-state NMR studies of membrane proteins.

In principle, a single three-dimensional correlation spectrum of an oriented sample of a uniformly ^{15}N labelled protein provides sufficient information in the form of orientationally dependent frequencies for each amide site to determine the complete structure of the polypeptide backbone. The two-dimensional ^1H - ^{15}N heteronuclear dipolar- ^{15}N chemical shift PISEMA spectrum in **Figure 5a** was obtained from a uniformly ^{15}N labelled sample of the 50-residue fd coat protein in oriented bilayers; it contains resonances from all of the amide backbone (and side-chain) nitrogen sites. The resonances in the box in the upper left are largely from residues in the trans-membrane hydrophobic α -helix, and the resonances in the box on the right are from residues in the in-plane amphipathic α -helix. The two-dimensional PISEMA spectrum is generally well resolved, although there is some overlap among the resonances from residues in the trans-membrane α -helix because their peptide bonds have similar orientations, approximately parallel to the magnetic

field. Two-dimensional planes extracted from a three-dimensional correlation spectrum of the same sample are shown in **Figure 5b** and **5c**. The spectral regions in the planes correspond to the boxed regions of the complete two-dimensional spectrum with which they are aligned. There are very few resonances in the spectral regions in **Figure 5b** and **5c** because only those resonances with a specific ^1H chemical shift, the third frequency in the three-dimensional spectrum, appear in each plane. These data illustrate how the three-dimensional correlation experiment contributes to these studies. First, it provides a substantial increase in resolution by separating resonances based on their ^1H chemical shift frequencies. Second, it enables the direct measurement of three orientationally dependent frequencies for each resolved resonances, the ^1H chemical shift, ^1H - ^{15}N heteronuclear dipolar coupling and the ^{15}N chemical shift. Because the orientation of the protein-containing bilayers is fixed by the method of sample preparation, these frequencies can be used to determine the orientation of each peptide plane with respect to the applied magnetic field, since the magnitudes and orientations of the spin-interaction tensors for the amide sites in the molecular frame are known. Structures are then determined using the frequencies associated with individual resonances that have been assigned to specific residues as angular constraints. Using this approach the three-dimensional structure of the M2 trans-membrane segment from the acetylcholine receptor in oriented bilayers was determined. The ^{13}C chemical shift and ^2H quadrupolar coupling frequencies measured from selectively or specifically labelled samples in separate experiments also provide valuable structural information, and have been used together with the ^{15}N chemical shift and the ^1H - ^{15}N heteronuclear dipolar coupling to determine the structure of the gramicidin channel at high resolution.

Amplitude of motion–order parameters

Partial but fast ($\tau_c < \Delta\nu_{Q(\max)}$; $\Delta\text{CSA}_{(\max)}$) motional averaging of spectral anisotropy permits an order parameter, and hence an angle of motional amplitude with respect to a fixed axis (the membrane normal), to be determined. Direct measurements of order parameters from the powder patterns of random bilayer dispersions of deuterated lipids are conveniently made from the measured quadrupole splittings ($\Delta\nu_q$) (**Figure 2**), determined from the spectral maxima, corresponding to the 90° -orientational spectral components. Thus:

$$\Delta\nu_q = \left(\frac{e^2 Q q}{b} \right) (3 \overline{\cos^2 \theta} - 1)$$

where $(e^2 Q q / b) = 127 \text{ kHz}$ and thus

$$|S| = \frac{(\Delta\nu_q)_{\text{obs}}}{(\Delta\nu_q)_{\text{max}}}$$

and so $1 > |S| > 0$.

The order parameter profile (S at various positions of measurement) usually observed for lipid acyl chains displays a plateau for lipid methylenes in the upper part of the bilayer (C_2 – C_{10} ; $S \sim 0.4$) as a result of water penetration and ordering of the upper part of the bilayer and then a decrease to the centre of the membrane (C_{10} – C_{16} gives S values of 0.4 – 0.1) (**Figure 6**). The discontinuity in S -profile at C_{10} – C_{12} corresponds to the main position of unsaturation in natural membranes. At this position, the static kink in the chain contributes geometrically to the angle about which motional averaging occurs, thereby reducing the molecular order

Figure 6 The measured deuterium order parameters, S_{CD} for the *sn*-1 (saturated) and *sn*-2 (unsaturated, C9=C10) bilayers of phospholipids specifically deuterated in their acyl chains, showing the consequence of the presence of double bonds causing the staggered conformation of the chains thus affecting the quadrupolar averaging (b), even though the molecular order parameter, S_{mol} , remains for each chain (a). Reproduced with permission from Seelig J and Seelig A (1977) Effect of single cis double bond on the structure of a phospholipid bilayer. *Biochemistry* 16: 45–50.

Figure 7 Deuterium NMR quadrupole splittings ($\Delta\nu_q$) of the β -CD₂ group plotted against the corresponding splitting for the α -CD₂ group of dipalmitoylphosphatidylcholine with $-(\text{P}(\text{O}_4)^- - \alpha\text{CD}_2 - \beta\text{CD}_2 - \text{N}^+(\text{CH}_3)_3)$ in bilayers for a range of ions at constant ionic strength, $I = 1.05$ M and at 59°C , showing the sensitivity of lipid head group orientation to surface charge. Reproduced with permission from Akutsu H and Seelig J (1981) Interaction of metal ions with phosphatidylcholine bilayer membranes. *Biochemistry* 20: 7366–7370.

parameter (S_{mol} determined from $\Delta\nu_{q(\text{obs})}$), since:

$$|S_{\text{mol}}| = |S(\text{orientation})| \times |S(\text{amplitude})|$$

Labelled ^2H lipid head groups give rise to small ($\Delta\nu_q < 10$ kHz) quadrupole splitting, since their amplitude of motion with respect to the membrane normal is large, and their axis of averaging is not the membrane normal. In this case, the angle of molecular averaging cannot be uniquely determined, but the experimentally determined $\Delta\nu_q$ values can be useful in studying ion binding (Figure 7), peptide and protein interactions, and electrostatic interactions, since the phospholipid head group acts as a molecular voltmeter and sensor of interfacial pH at the bilayer surface.

Distance measurements within membranes

In MAS NMR, sample spinning averages out the dipolar couplings which are required for distance determinations. However, internuclear distance measurements can be made using rotational resonance (R^2) for homonuclear spins and REDOR for heteronuclear spins, in which the dipolar couplings are reintroduced into the spectrum under special spinning conditions. By spinning (at a speed of ω_r) the sample at multiples (n , where $n = 1, 2, 3, 4, \dots$) of the chemical shift difference (Δ in Hz) between a specific spin pair such that $\omega_r = n\Delta$, then transfer of magnetization occurs between the spin pair, and the dipolar interactions
